The author wishes to express his appreciation to H. G. Russell, G. R. Carlisle, and T. R. Greathouse for their contributions to this circular in the form of ideas, suggestions, and printed materials ("Ewe Flock Management in the 60's").

Urbana, Illinois
January, 1967

Acts approved by Congress May 8 and June 30, 1914.
EWE FLOCK MANAGEMENT

By G. E. Ricketts

Good management is the key to an efficient and highly profitable ewe flock. Too many flocks are used merely as fencerow scavengers. As a result, their productive ability and income potential are either completely overlooked or grossly neglected.

Most Illinois farm flocks are supplemental farm operations, but there are some farms on which sheep are the major livestock enterprise. Sheep economically convert available pasture and roughage into pounds of lamb and wool, and help provide for a more even distribution of farm labor requirements. Ewe flocks call for a smaller investment and show a greater return per animal unit than a beef cow herd. Many flocks are too small for economical production and should be enlarged to contribute a greater percentage of the livestock income, and therefore warrant more management attention.

Sheep are ideally suited to grassland agriculture, but there has been an increasing interest in partially confined or drylot operations, especially in the cash grain areas of Illinois. Most of these operations will have facilities for 150 ewes or more.

The trend in the sheep industry, as in beef and swine, is an ever-increasing demand for the production of a meat-type animal. The high degree of finish to which livestock have been fattened in the past is no longer tolerated. The housewife wants less waste fat on the meat she buys. In addition, extremely fat animals are not economical to produce, because an animal needs 2½ times as much energy to produce a pound of fat as to produce a pound of muscle and bone.

What is a meat-type lamb? At present we believe it is an efficient, rapid gaining lamb that will produce a highly desirable carcass, containing a minimum amount of fat and a maximum amount of muscle, especially in the leg and loin areas. To be more specific, lambs should weigh at least 90 pounds at 120 days of age, yield 50 percent or more when slaughtered, carry no less than 0.15 inch and no more than 0.35 inch of subcutaneous fat, have at least 2.5 square inches of loin eye, and grade at least choice on quality and conformation. Keep the meat-type lamb in mind when setting your production goals.

RETURNS FROM COMMERCIAL EWE FLOCKS IN ILLINOIS

There is a wide range of gross returns per ewe in Illinois ewe flocks. A summary of the 1965 production records for 113 flocks involved in the Illinois Sheep Production Project showed gross returns ranged from a high of $56.72 to a low of $18.18. By gross returns is meant the proceeds from the sale of lambs and wool and the incentive payments for both. As you can see, these figures mean that some flock owners received more than three times as much income per ewe as others. Twenty-four flocks had gross returns of more than $40 per ewe and five flocks had gross returns of more than $50 per ewe. Some results of the project summary that help explain the large amount of variability in flock returns are:

- Percent of ewes failing to lamb: 0 to 38.5
- Percent of lamb crop born: 86 to 194
- Percent of mortality (birth to weaning): 0 to 42.9
- Lamb prices received (per lb.): $0.18 to $0.295
- Price received for Easter lambs (per lb.): $0.32 to $0.37
- Lamb selling weights (lb.): 50 to 130
- 12-month fleece weights (lb.) per ewe: 6.0 to 16.0
- 12-month fleece weights (lb.) per ram: 6.0 to 24.0

It is apparent from the information obtained in the summary that well-managed flock operations can be highly productive and profitable.

What is needed to get the highest gross return per ewe? The summary of project records indicates that (1) all ewes should lamb, (2) a high percentage of multiple births is needed, (3) lamb mortality must be kept low, (4) lambs must be marketed at desirable weights and when prices are highest, (5) heavy-shearing ewes and rams are highly essential, and (6) wool must be marketed in a desirable condition and at the highest possible price per pound. Essentially it all boils down to good management in all phases of the sheep enterprise.

SYSTEMS OF SHEEP PRODUCTION

Most Illinois farm flocks are commercial operations, used primarily to produce market lambs and wool. The most important factors in market lamb production are the number of lambs raised per ewe and the ability of lambs to gain rapidly from birth to marketing.

Commercial flocks use western ewes, native ewes, or both. Flock owners who use western ewes feel these sheep have several advantages
over native ewes. They are available in larger numbers, can be obtained in more uniform groups, have fewer parasites, and are usually more hardy.

Native ewes generally cost less per head, often show more desirable mutton conformation, and are often more productive. Many flock owners with native ewes also produce their own replacements.

This outstanding flock of Dorset ewes indicates the length of body, thickness, ruggedness, soundness, and uniformity that are highly desirable in both purebred and commercial ewes.

Northwest ewes are preferred over southwest ewes because northwest ewes generally are larger, show more desirable mutton conformation, produce more wool, and have fewer parasites. However, southwest ewes need less feed and the initial cost per head is less. In recent years the southwest ewes have been improved in size and quality.

Mature ewes with solid mouths are available on the market each fall. If these are ewes that have been sold in order to decrease flock numbers they may be a good investment. However, many of these marketed ewes have been culled because they did not lamb, did not raise a lamb, or raised lightweight or inferior-quality lambs, and are not good breeding ewes.

Broken-mouth ewes and gummers are also available. Most of them have been good producers or they would not have been retained so long in the original flock. These ewes generally require extra care and management. If a person buys these ewes, he should count on only one or two lamb crops and then sell the ewes as well as the lambs.

The main purpose of maintaining purebred flocks is the production of breeding stock for commercial flocks and for other purebred flocks. A purebred flock can help a farmer increase his income without increasing the number of ewes he owns. It takes good individual sheep but does
not require a large flock. The purebred flock owner must be a good sheepman and must be able to sell. He must also be honest in his dealings and have breed improvement as one of his major goals. When selecting a breed, consider the market for breeding stock and the availability of breeding stock in your area. If there is a demand for several breeds, the choice of breed can be based on personal preference and availability.

SELECTION OF EWES AND RAMS

Selecting good breeding stock to start or expand an operation, whether purebred or commercial, is an extremely important part of livestock management. To make the most rapid progress in flock improvement, you must use good stud rams, and it is here that many producers are most negligent. Selection of a stud ram is a major decision and not something to be done on the spur of the moment. You can’t expect to buy an outstanding sire for market price. Neither can you expect outstanding results from a scrub. Give some time and thought to the selection and management of your stud ram.

Criteria for selecting breeding stock:

1. Growthiness (size for age). Select rapid-gaining sheep that meet your other standards. Rapid-gaining animals usually make the most efficient use of feed and can be marketed at a younger age. A slow-growing lamb is not so profitable as a fast-growing lamb. Set as your goal to have twin lambs weighing at least 85 pounds and single lambs weighing at least 95 pounds at 120 days of age (if creep-fed), and then select breeding stock with the gaining ability to produce such lambs.

2. Soundness.
   a. Feet and legs. When their feet are well trimmed, sheep should be able to stand squarely on them. Select sheep that have short, strong pasterns and straight legs with plenty of width between them. Crooked legs and weak pasterns can decrease an animal’s ability to move and perform normally, and can decrease its years of reproductive usefulness.
   b. Mouth. Check the sheep’s mouth for age, condition of the eight incisors, and jaw malformations like monkey mouth or parrot mouth.
   c. Udder. If ewes have produced at least one lamb crop, check their udders to be sure that both teats are present and functional and that there are no lumps or hard areas.
   d. Testicles. Check the ram to be sure both testicles are present, fully descended, sound, and nearly equal in size.
3. **Conformation.** The ideal conformation probably varies from one breed to another. However, there are times when you can find about as much variation between animals of the same breed as you can between different breeds. In general, a sheep with good conformation has the following qualities: (a) wide chest; (b) smooth shoulders; (c) fullness through the heart area and the spring of ribs; (d) long, deep body; (e) wide and straight top; (f) long, wide, and level rump; (g) deep, thick, and full leg of lamb or mutton; and (h) overall balance (blending together of body parts).

4. **Condition of birth (single, twin, or triplet).** Your first choice should always be ewes and rams of multiple birth. Even though the heritability of multiple birth is considered low, progress can be made in increasing lambing percentage by selecting for twinning. Under midwestern conditions, a good set of twins is more profitable than a good single lamb. The idea that twinning is economically important is not new; in 1837 Youatt wrote: “Ewes yearly by twinning/Rich masters do make; /The lambs from such twinners/For breeders go take.”

5. **Previous performance.** When you buy breeding stock, get all the performance information you can—such factors as weight at 90 or 120 days and weight at one year of age. Find out the performance of their progeny, if any. Also check the performance of sires and dams. Some breeders have carcass information available, so check on this also.

6. **Substance (amount of bone).** Select heavy-boned sheep. In general, heavy-boned animals do better than fine-boned ones.

7. **Wool.** Select heavy-shearing sheep that have dense, uniform, high-quality fleeces, with no dark fiber. This is one factor that is often neglected in sheep selection, but should not be since wool makes a sizable contribution to the gross income from a sheep enterprise.

8. **Age.** Select the younger ewes because they have more productive years ahead than older ewes. Even though yearlings cost more than older ewes, their cost per lamb produced is usually less. Yearling ewes have more productive years ahead of them, have sounder udders, and have a lower death loss. Ewes generally reach peak productivity at four to six years of age.

   The age of the ram will determine how many ewes he can service. Under normal field mating conditions a ram lamb can be used on about 15 ewes, a yearling ram on 25 to 35, and an aged ram on 35 to 45. A good rule of thumb is three mature rams for every 100 ewes in the breeding flock.

   The age of sheep can be determined by their teeth. Lambs are born with eight milk teeth, or incisors, arranged in four pairs in the lower jaw.
The age of sheep can be determined by their teeth, as is illustrated here.

The center pair is shed at approximately one year of age and replaced by larger, permanent teeth. When the sheep is two years old, the second pair of permanent teeth replace the second pair of milk teeth; and at three and four years the third and fourth pairs of permanent teeth appear. At four years of age the sheep has a "full mouth." A ewe often loses her teeth at five to seven years of age. When a ewe loses part of her incisor teeth, she is called a "broken-mouth" ewe. Ewes with no incisors are called "gummers."

9. **Sex character.** Ewes should look feminine and rams should look masculine. Masculine rams are generally more rugged, active, and aggressive than rams which lack this quality.

10. **Breed type.** Breed type is an important consideration in pure-bred livestock. Without it breed identity is lost. Even though breed type is important, do not get carried away to the point where you forget all else. It needs to be appraised along with the other factors listed here.

This ram indicates the growthiness, ruggedness, muscling, soundness, length of body, balance, and masculinity that are desirable in a stud ram. He is a twin and weighed 295 pounds at 17 months of age.
The fact that growthiness, desirable type, and desirable conformation can all be contained in the same sheep is pointed out in this outstanding set of twins. The ram lamb weighed 132 pounds at 103 days of age and the ewe lamb weighed 117 pounds at 105 days of age. Both lambs did exceptionally well on the show circuit.

USE OF PRODUCTION RECORDS

Production records, if well kept, can be a useful tool to both commercial and purebred flock owners. They are especially important in flocks that produce breeding stock or that retain ewe lambs for replacements.

Production records can be used to:

1. Measure flock productivity.
2. Provide permanent records.
3. Identify top-producing ewes so their lambs can be kept for breeding stock.
5. Evaluate ram performance.
6. Show differences in gaining ability of lambs.
7. Supplement what can be seen with the naked eye.

The records do not have to be kept in great detail. Include the following information on the record: ewe identification number, date of lambing, number and sex of lambs born, sire of lambs, age and weight of lambs weaned, and fleece weight of the ewe. Any additional information you want can also be included.

You should carry out a production testing program on your purebred flock if you expect to be a progressive breeder. Such tests will enable you to evaluate your breeding program, make sounder replacement selections,
and provide information that will aid in selling breeding stock. If you are a purebred breeder, you should also obtain carcass information on some of your lambs to determine if you are producing the desired meat-type lambs.

Tables 1 and 2 point out the large differences in ewe productivity and lamb gains that can exist within a flock. Without accurate production records, it would be extremely hard to determine which ewes were the high or low producers. This information was taken from the production records of a flock containing 105 ewes. Male lambs were castrated at 10 days of age and all lambs were weaned at 90 days of age.

Without some sort of production records it is difficult to determine if progress is being made in flock improvement. Such factors as weaning weights, fleece weights, lambing percentage, and percentage of death loss have a direct effect on income and profit from the enterprise.

On the next two pages are copies of a Barn Record Form and an Individual Ewe Record that are available from the Livestock Extension Office, 326 Mumford Hall, Urbana, Illinois 61801. Example records have been placed on these forms for illustrative purposes.

1/ Multiply the fleece weight by 3.
2/ Add 6 points for each lamb born a twin or triplet and raised a single.
3/ Add 4 points for each ewe lamb and wether lamb.
4/ Add 3 points for each lamb raised by a ewe two years old or younger or a ewe seven years of age or older.
5/ To determine the ewe index, add the total pounds of lamb at 90 days + wool credit + additional credit.
BREEDING SEASON CONSIDERATIONS

Lambing Season

One of the major decisions a flock owner needs to make is whether to plan an early-lambing program (late December to early March) or a late-lambing program (starting in late March). Early lambing has these advantages: lambs usually are sold on a higher market; lambs will gain more rapidly; hot weather and internal parasites do not pose a major problem; lambs can be sold without putting them on pasture; and labor requirements for lambing come at a slack time of the year.

Late lambing has the following advantages: building and equipment requirements are less; feed costs per ewe are lower; and lambs can make maximum use of pasture forage and can be marketed directly from pasture with a minimum amount of grain feeding.

This highly productive Rambouillet ewe has raised nine lambs from six lambings and has averaged 12 pounds of wool per year. Recently she has been placed on an accelerated lambing program and has lambed three times in the past two years. The three lamb crops are shown with her in the above photo. The two sheep on the left are twins born October 5, 1964. The ewe in the center is a single born July 24, 1965. The twin lambs on the right were born March 13, 1966. At the time this photo was taken the ewe was to lamb again in November of 1966.
In recent years there has been increased interest in fall lambing (September 1 to December 1) and also in accelerated lambing (three lamb crops in two years). The advantages of fall lambing are: favorable weather; better use of equipment; lower feed and labor requirements; good prices for lambs; and the possibility for accelerated lambing. Disadvantages are: a higher percentage of ewes fail to lamb; smaller birth weights; lower lambing percentages; and at times poorer milking ewes.

Some flocks have been put on an accelerated lambing program with fairly good success. This type of program is a must for those who go to a drylot or semi-confinement type of operation. Certain breeds are more adapted to fall lambing and accelerated lambing than others. Sheep of Rambouillet and Dorset breeding seem to have the lead in this respect. Many Hampshire and Corriedale flocks have quite a few fall lambs. Some of the other breeds are also producing a few fall lambs.

**Flushing the Ewes**

Feeding a ewe so it rapidly improves in condition from ten days to two weeks before breeding (commonly known as flushing) may increase the lambing percentage by 10 to 20 percent. However, this increase will not occur if ewes are already in a high condition prior to breeding. Ewes that become too fat may not breed at all. To flush ewes, let them graze better pasture or feed them $\frac{1}{2}$ to $\frac{3}{4}$ pound of corn or oats, or a mixture of the two, per head per day. Use some caution when flushing ewes by turning them onto lush legume pastures. During years of heavy rainfall, such pastures often contain a high level of coumestrol (a plant estrogen) that can cause delayed conception.

**Tagging the Ewes**

All ewes that are in long fleece or have a lot of manure around the rear end should be tagged before the ram is turned in. Tagging means trimming the wool around the dock area so it will be easier for the ram to do a good job of getting the ewes settled.

**Ram Management and Breeding Records**

Shear your rams four to six weeks before the breeding season if you expect maximum breeding results. Rams in long fleece during hot weather may become infertile because of high body temperature, and it may take approximately six weeks for them to regain their fertility. Some flock owners have improved breeding performance and their lamb crops by turning rams in with the ewes only at night, and then keeping the rams in cool quarters during the day.

New rams should not be turned in with the ewes immediately upon
arrival at the farm, but should be allowed at least one or two weeks to become familiar with their new environment. The same is also true of show rams. Gradually lower the condition of these rams and give them plenty of exercise for several weeks before you turn them in with the ewes.

It is advisable to use some system of marking so you will know when the ewes are bred and whether the ram is doing an effective job. A marking harness with crayons can be used for the ram or his brisket can be smeared with a marking pigment. In either case, whenever a ewe is bred her rump will be marked. Change the marking crayons or the brisket smear pigments every 17 days. For the smear pigment, you can use yellow ochre and old crankcase oil, venetian red and crankcase oil, or lamp black. Apply it to the brisket every second or third day.

The use of a marking harness is a very satisfactory means of determining when the ewes are being bred and whether or not the ram is doing an effective job of breeding. Notice the proper position of the harness as shown here and the fact that the ram has been shorn prior to the breeding season.

It will be easier to keep an accurate breeding record if you paint-brand the ewes. Use any good scourable paint-branding fluid. The ewes can be paint-branded in several places such as the side, back, or shoulder, however the back is most commonly used. In this way when a ewe is marked by the ram she can be easily and quickly identified.

Animal scientists used to think the ram had no effect on lambing percentage, but in recent years information has been accumulating that indicates this is not necessarily true. Recent reports indicate that the ram
can have an important influence on the reproductive performance of the ewe. Some rams consistently sire more multiple births than others.

Effect of Temperature on Embryonic Mortality

Extremely hot weather at breeding time can cause increased embryonic mortality. Sheep need trees, a shed, or some other artificial shelter so they can get out of the sun and keep as cool as possible. Ewes or rams that have heavy fleeces or are in high condition may have an increase in body temperature when the air temperature is high. Under stress conditions fertility is impaired and an increase in loss of early embryos results.

FEEDING THE EWE FLOCK

When you develop a feeding program for your ewe flock, take advantage of their ability to efficiently use large quantities of roughage and pasture. A sound feeding program should include maximum use of high-quality hay (legume or mixed), silage (corn, grass, or legume), or haylage. Two of the most critical periods of the year, so far as nutrition is concerned, are late pregnancy and early lactation. If a ewe is expected to deliver large, strong, healthy lambs and provide a heavy flow of milk, then adequate nutrition must be provided before and after lambing.

Trace-mineralized salt or a salt-mineral mixture should be fed free choice throughout the year. Sheep should also have plenty of clean, fresh water available at all times. During cold weather use water heaters to keep water from freezing and to insure adequate water intake.

Concentrate Rations

The concentrate ration can be very simple. Make maximum use of home-grown grains. If a high-quality legume or mixed hay is fed then no protein supplement is needed during gestation or lactation. Corn, oats, and barley are excellent cereal grains for feeding sheep and the combination of any two or all three, can make up the concentrate ration. A commonly used ration is a mixture of half oats and half shelled corn. Sometimes bran is used to make up 10 percent of the ration, primarily because of its laxative properties. When poor-quality roughage is fed, 15 to 20 percent of the concentrate ration should be a protein supplement (soybean meal, linseed meal, or a commercial protein supplement).

Feeding During Gestation

Whether you should give ewes supplemental feed during early pregnancy depends on the availability of feed in the form of pasture,
stubble fields, and stalk fields. If the roughage supply in the fields is not adequate and the ewes are not gaining weight, then feed one or two pounds of legume hay per head per day.

Feed a concentrate ration during the last six weeks of pregnancy to provide an additional supply of energy to meet the demands of the rapidly developing fetus. About two-thirds of the birth weight of a developing fetus is gained during the last six weeks of pregnancy. It is usually thought that a ewe should gain from 20 to 30 pounds during pregnancy.

Inadequate nutrition during the last six weeks of pregnancy may result in the following:

1. A higher percentage of ewes with pregnancy disease.
2. A decrease in birth weights.
3. Weaker lambs at birth.
4. An increase in infant lamb mortality.
5. Slower gaining lambs.

During the last six weeks of pregnancy, feed from ½ to 1 pound of a concentrate ration and 3½ to 4 pounds of legume or mixed hay per head per day. The exact amount to feed depends on the weight and condition of the ewes. Silage can be substituted for hay at the approximate rate of 2 to 3 pounds of silage for each 1 pound of hay replaced, depending on the moisture content of the silage. Keep in mind that corn silage is low in protein and calcium, so a protein-mineral supplement must be added unless half of your roughage is legume hay.

Wisconsin studies show that ewes which ate 8 pounds daily of grass silage (50 percent moisture content) during late gestation and 12 pounds daily in early lactation produced as well as ewes that received 5 pounds of legume hay and 1 pound of grain daily through both periods.

**Feeding During Lactation**

Lactation places a greater demand on the ewe than pregnancy, and increases the level of nutrients needed. A 140-pound ewe in early lactation needs about 70 percent more protein than in early pregnancy, and she needs 19 percent more protein than in late pregnancy (at which time the ewe would weigh about 160 pounds). The total daily nutrient requirements (TDN) are increased by approximately 82 and 24 percent, respectively. After about 60 to 70 days of lactation, the nutrient requirements are less because of declining milk production, so the amount of concentrate fed can be decreased at this time.
Note the thrifty condition of these fall-born lambs, indicating that the ewes are good milkers and have been well fed.

During the first 60 to 70 days of the lactation period, continue to feed 3½ to 4 pounds of high-quality legume or mixed hay, but increase the amount of concentrates up to 1½ to 2 pounds per head per day. Keep in mind that the actual amount depends on the weight and condition of the ewes. Small ewes require less than the recommended amounts and very large ewes require more. Separate ewes that are nursing more than one lamb and feed them an additional ½ pound of concentrate mixture. Keep in mind that the feeding value of 2 to 3 pounds of silage is about the same as 1 pound of hay. By the time lambs are between one and two months of age, they will be eating quite a bit of the ewes' feed, and you must keep this in mind to adequately meet the ewes' requirements.

After the first 60 to 70 days of the lactation period feed the ewes the same ration you fed them during late pregnancy—3½ to 4 pounds of legume or mixed hay and ½ to 1 pound of a concentrate mixture. Additional feed at this time will only allow the ewes to put on excess fat and will increase the cost of production.

As soon as the ewes can be turned out to pasture full time, no additional roughage or grain is needed as long as there is sufficient pasture.

To be a good shepherd you must use your eyes, your hands, and a scale, if one is available, to find out how the ewes are doing in relation to changes in weight and condition. By keeping up to date on the changes in your flock, you can alter your feeding program accordingly.
EWE MANAGEMENT DURING GESTATION

Exercise

Pregnant ewes should have plenty of exercise. Some flock owners feed hay or grain some distance from the barn so the ewes will be forced to exercise. The last month of pregnancy may present the most problems. Ewes that are extremely fat or that are carrying twins or triplets may become very sluggish. Watch them carefully and force them to exercise. Many of these ewes will eat less than they should and they are the ones that may develop pregnancy disease (pregnancy toxemia or ketosis).

Pregnancy Disease

Pregnancy disease commonly occurs a few weeks before lambing. Most of the affected ewes are carrying twins or triplets. The disease is related to the metabolism of carbohydrates late in pregnancy. Because of the large amount of abdominal space occupied by the rapidly developing fetus, the ewe may have difficulty eating enough to supply her own needs and those of the unborn lambs, especially if only roughage is fed.

In the early stages of the disease the ewes are less active than the rest of the flock and walk very slowly. Later they become weaker, walk stiffly, have difficulty rising, and may stand with their heads against some object. As the disease progresses, they cannot rise and they lie with their heads turned to the side. Other symptoms are rapid breathing, blindness, and grinding of the teeth. In advanced stages the breath may have a characteristic sweetish odor that helps to identify this disease. If affected ewes are not treated as soon as the disease is noticed, a high percentage of them will die unless lambing is only a few days away. They will generally recover after lambing if their condition is not critical at lambing time.

Ewes with pregnancy disease should be treated when they are in the early stages of the disease for most effective treatment. You can use several treatments, such as drenching the ewes with (1) 3 to 4 ounces of glycerol or propylene glycol twice daily, (2) ½ pint of molasses twice daily, or (3) ½ pint of a 25- to 50-percent fructose solution twice daily.

Preparing the Lambing Quarters

Sheep do not need elaborate or expensive housing and equipment. Whether you are following an early- or late-lambing program will determine how tight and free from drafts the building should be. Lambing pens (4 feet by 4 feet or 4 feet by 5 feet) should be set up before the lambing season in a draft-free area of the barn. Even though the average length of gestation is 147 to 148 days, some ewes may lamb a week early, so it pays to be prepared.
These lambing pens are clean and well bedded with water available for the ewes. The ewes have been paint-branded for easy identification.

**Shearing Before or After Lambing**

Many flock owners shear their ewes several weeks before lambing, and this practice has several advantages:

1. It eliminates the need for crutching.
2. It is easier for lambs to nurse and is more sanitary.
3. Fleeces contain less dirt and manure.
4. More ewes can be put into a limited space.
5. It is easier to spot ewes that are close to lambing and those with udder problems.
6. The barn is dryer and less bedding is needed.

There are also several disadvantages:

1. A good, warm building is needed.
2. Fleeces will not have as much grease weight.
3. Sheep are harder to shear in cold weather.
4. If ewes are sheared too near lambing time and are handled roughly, some lambs may be born prematurely.

**Crutching**

If you do not shear ewes before they lamb, at least crutch them out. Crutching means to shear around the udder, between the legs, and around the dock. If there is extensive wool covering on the face, it would be a good idea to shear the head also.
EWE MANAGEMENT DURING LAMBING AND LACTATION

Lambing time is a very critical period of the year, because at this time you can “make or break” the future productivity of your flock. The higher the percentage of lambs born alive and reared to marketing time, the greater the gross returns from the enterprise.

Lambing Time Suggestions

1. Watch ewes closely and give assistance if needed.
2. When a ewe has difficulty, find out whether the lamb is being delivered in normal position (head between and slightly above the front feet). If not, proceed cautiously. Difficult lambing may be caused by any of the following conditions:
   a. The lamb is extra large, especially its head and shoulders.
   b. The ewe has small pelvic area.
   c. The ewe fails to dilate.
   d. The lamb comes backwards (breech birth).
   e. One or both front legs are bent back.
   f. The head is bent back.
   g. The lamb comes hocks first.
   h. If the ewe is carrying two lambs, their legs may become tangled; or, if the two lambs are side by side, the ewe may try to deliver both at the same time.
3. Just before or after the ewe lambs, place her in a lambing pen.
4. Check the udder to see if colostrum is available, and check the teats to be sure they are open.
5. Be sure the ewe owns her lambs and allows them to nurse before you leave.
6. If lambs are weak, help them nurse.
7. If it is extremely cold, provide a heat lamp for each lambing pen.
8. Ear-tag lambs and record information on your barn records.
9. You can remove ewes with healthy single lambs from lambing pens after one day, and ewes with healthy twins after two days.

Value of Colostrum

The first milk the ewe produces after lambing is called colostrum. It differs a great deal in chemical composition and biological properties from the milk secreted several days after lambing. It is highly essential for lambs to get some colostrum as soon as possible after birth, because it provides energy, protein, vitamins, and minerals, as well as antibodies.
that help them resist infection. For example, lambs are born with a low level of vitamin A. Colostrum is rich in vitamin A and is essential to build up lambs' vitamin A reserves. Ohio studies indicate that ewes delivering twins have approximately 46 percent more vitamin A in their colostrum than ewes delivering singles.

Some flock owners freeze the colostrum from ewes that deliver dead lambs or those that lose their lambs. They then use it for orphan lambs or lambs from ewes that have no colostrum available soon after lambing.

**Udder Problems**

The need to keep the ewe's udder working well cannot be overemphasized, because milk is the lamb's main food for at least the first 30 days. There is a close relationship between milk yield and lamb growth and development, especially during the first part of the lactation period. The capacity of the offspring to consume milk is one of the principal factors that govern the amount of milk produced by the dam. Ewes with twins produce about 50 percent more milk than comparable ewes with singles.

Observe ewes and lambs carefully throughout the lactation period to detect sickness or other disorders before they become major problems. One of the potential trouble spots is the udder. If it becomes injured or infected and the condition is not treated early, the ewe may lose the milk-producing ability of one or both sides of the udder.

Mastitis can become a serious problem and may even cause death. One form is very toxic and, if not treated at once, ewes may die within two or three days after the infection starts. When a case of mastitis occurs, isolate the ewe and her lambs from the rest of the flock until the infection is under control. Udder infections can be spread when lambs that belong to infected ewes nurse other ewes. Lambs can also injure the udder with their sharp teeth. If these injuries are not treated early, they may become so painful when the lambs nurse that the ewe will automatically wean them. Udder sores provide excellent avenues for harmful bacteria to enter the body. Keeping the barn well bedded will help cut down udder problems.

**Helping Ewes Own Their Lambs**

Persuading a ewe to claim her lamb or lambs can sometimes be a real headache. This is generally more of a problem with ewes lambing for the first time than it is with older ewes. If you have trouble with a ewe two years in a row, it would be best to sell her.

There is no clear-cut answer to why ewes fail to claim their offspring. Some of the situations that may cause a ewe to disown one or all of her lambs are:
1. A ewe may deliver one lamb in one part of the barn and deliver a second lamb in another part of the barn.

2. One of a set of twins may wander away from its mother before she has fully recovered from delivery.

3. The ewe may have a very painful udder caused by swelling, caking, or infection.

4. The teats may be cut or chapped, causing the ewe a great deal of discomfort.

5. A ewe that has been in labor for a long period of time may not be interested in her lamb for quite a while after delivery.

6. Sometimes a ewe may run a high temperature for several days after lambing and not show much interest in her lambs.

7. Sometimes you may have problems with ewes that are very nervous and flighty.

8. Some young ewes lambing for the first time may be frightened by the lambs they have given birth to.

It takes a lot of patience to work effectively with a ewe that disowns her lamb. Keep in mind that it is much easier for the ewe to raise her lamb than for you to raise an orphan. There is no guaranteed method of getting a ewe to claim her offspring. But flock owners have reported satisfactory results with one or a combination of the following measures:

1. Tie the ewe in the pen until she allows the lamb to nurse.
2. Put a dog near the pen with the ewe and lamb.
3. Rub the ewe's nose and the lamb with some of the ewe's milk or with kerosene or oil.
4. Household deodorizer sprays may be sprayed on the lamb and on the ewe's nose.
5. Blindfolding the ewe is also helpful at times.

**FEEDING AND MANAGEMENT OF LAMBS**

**Lamb Mortality**

Lamb survival and performance determine to a large extent how profitable a sheep enterprise will be. Lamb mortality studies show that 50 to 70 percent of lamb death losses occur in the first three to five days after birth, and 80 to 90 percent occur during the first month. These figures indicate that it is extremely important for each lamb to get a good start and that the first few days are critical ones. These studies also show that the four main causes of lamb losses have been weak lambs, starva-
tion, stillbirths, and pneumonia. Male lambs are reported to have a higher mortality rate than females, and twins have a higher mortality rate than singles. In many flocks a higher death loss occurs among lambs born in the second half of the lambing season.

**Disinfecting the Navel**

It is a good practice to disinfect the navel cord of all lambs soon after birth with tincture of iodine or another good antiseptic to prevent navel ill (joint disease), which is caused by bacterial infection. The disease causes a stiffness and swelling of the joints of the legs. Sometimes the navel area also becomes infected.

**Inverted Eyelids**

If not corrected, inverted eyelids (entropion) can lead to total blindness. Sometimes lambs have this condition at birth; others may not be affected until they are one or two weeks old. Unless it is severe it can usually be corrected by catching the lamb several times a day and working the eyelid outward. Use an eye ointment or powder to help eliminate infection caused by irritation. If the condition is severe and does not respond to this treatment, try one of these remedies: use adhesive tape to hold the eyelid in place for several days; use metal clips (surgical type) to hold the eyelid back; or clamp the excess fold of skin below the eyelash with a small burdizzo to hold the eyelid in proper position. This is an heritable trait that should be discriminated against in the selection of breeding stock.

**Docking**

Lambs should be docked between 3 and 10 days of age. Several pieces of equipment can be used for this job including a pocketknife, burdizzo (emasculatome), elastrator (rubber rings), emasculator, and "all-in-one." Cut off the tail 1 to 1½ inches from the body. A good place is the junction or end of the caudal folds on the underside of the tail. Try to push the skin on the tail toward the body before cutting to allow enough loose skin to cover the stub and not expose the bone. Docking gives lambs a better appearance and decreases the chances of maggot infestation. Leaving tails on ewes can pose problems at breeding time and at lambing.

**Castration**

All male lambs that are to be marketed should be castrated before they are two weeks old. Normally wether lambs will not gain as fast as
ram lambs, and ram lambs are usually not discounted in price until after mid-May or early June. However, one of the major problems with ram lambs is that they continually pester the rest of the sheep and may settle some of the ewes if left with them too long (5 or 6 months), so it is best to castrate them. Wether lambs also usually have higher carcass grades and dressing percentages than ram lambs. Castration can be done with an elastrator, pocketknife, burdizzo, or “all-in-one.”

Creep Feeding the Lambs

Creep feeding is a means of providing supplemental feed for the lambs during the nursing period. It is usually more advantageous with an early-lambing program than with a late-lambing program. Advantages of creep feeding are: (1) it increases gains, especially for lambs from multiple births; (2) the lambs use supplemental feed more efficiently at this time than after weaning; (3) you can market lambs at a younger age; (4) earlier marketing usually means higher prices for lambs born early in the lambing period; and (5) creep feeding early lambs allows you to sell them without putting them on pasture, thus permitting more ewes to be carried on available pasture and reducing internal parasite problems.

Lambs will begin to nibble at grain and hay when they are about a week old. However, they will not eat much supplemental feed until they are about four weeks old. Set up the creep when the lambs are 7 to 10 days old, and put it in a convenient location close to the brood flock. Provide water in the creep or as close to it as possible. A heat lamp placed over the feeder will help attract the lambs, especially at night.
Here is an excellent creep that has been kept clean and well bedded. It provides grain, hay, and water and has a light which helps to attract lambs into the creep.

Sunlight shining into a creep during the day will also attract the lambs. The creep area should be kept well bedded and the feeders should be kept clean.

Make maximum use of home-grown grains and roughage when formulating the creep ration. Corn and oats as well as leafy, high-quality legume hay make excellent feed for young lambs. Barley can also be used, but may not be quite as palatable as corn and oats for the first couple of weeks.

Until the lambs are 6 weeks old the grain used in the creep ration should be cracked, crimped, or rolled unless a pelleted ration is used. After the lambs are six weeks old whole grain can be used unless it is extremely hard, and then the grain should be cracked, crimped, or rolled for several more weeks.

Although rolled oats are often too expensive to use, they are excellent in the creep ration or as a starter for lambs. Molasses is sometimes used in the creep ration, primarily as an appetizer or to hold down dust. If molasses is to be used it should make up 5 to 10 percent of the ration. Bran can also be included, making up 10 to 15 percent of the ration. Many people include bran in the creep ration because of its high palatability and laxative properties.
High-quality legume hay should be self-fed in either the long or pelleted form in addition to the concentrate ration, unless a high-roughage, complete-ration pellet is being fed. If you are not using legume hay or pellets, or if only poor-quality hay is provided in the creep, then include a protein supplement (soybean meal, linseed meal, or commercial supplement) in the ration. In this case the creep ration should contain 15 to 16 percent protein, and rations for early-weaned lambs (60 days old or less) should contain about 18 percent protein. Use the protein supplement that provides you with the lowest cost per pound of protein.

A very common concentrate ration used when high-quality legume hay is also available is 50 percent corn and 50 percent oats. When high-quality legume hay is not available or not fed then one of the following rations is commonly used: (1) 35 percent corn, 35 percent oats, 15 percent bran, and 15 percent protein supplement or (2) 40 percent corn, 40 percent oats, and 20 percent protein supplement. Ohio State University studies indicate that lambs can be creep-fed successfully on dehydrated alfalfa meal pellets alone until they are 8 weeks old. At this time corn and a protein supplement are also needed to get the highest gains and feed efficiency. Many people are using complete pelleted rations for creep feeding. Lambs on pelleted rations normally eat more feed daily and gain more rapidly. For a complete-pelleted creep ration, start with 65 to 70 percent roughage and gradually work down to 50 to 55 percent by the time the lambs are 2½ to 3 months old.

It is usually recommended that antibiotics be included in the creep ration at the rate of 15 to 20 grams per ton, which is the equivalent of 7.5 to 10 milligrams per pound of feed. Aureomycin (chlortetracycline) and terramycin (oxytetracycline) are the two most commonly used antibiotics in creep rations. Most studies have shown the following good results from the use of antibiotics: increased gains, improved feed efficiency, reduced scouring, lower death losses, and a more uniform group of lambs.

Creep rations do not have to be complex to be good. Research work in various states has indicated that lambs will perform as well on simple creep rations as they will on complex rations. However, there are times when a variety of ingredients or a change in ingredients may be needed if lambs go off feed. This is not as big a problem with lambs on creep feed as it is with weaned lambs.

Creep rations can be hand-fed or self-fed. Many sheepmen hand-feed until the lambs begin to eat regularly from the creep, and self-feed from then until weaning or marketing. The creep feeder must be kept clean at all times to get the largest consumption of the ration.
Raising an Orphan Lamb

One thing that helps get a lamb off to a good start is to make certain it gets some colostrum either from its mother or another ewe that has lambed about the same time. If a ewe loses her lamb within a day of birth, milk her out, freeze the colostrum, and use it when needed.

If you use cow's milk for the lamb, add one ounce of corn syrup to each pint of whole milk. Diluted or skimmed cow's milk should not be used since ewe's milk is normally much richer than cow's milk (ewe's milk is higher in fat and total solids). Good commercial milk replacers work well; however, they should be made slightly more concentrated than recommended for calves. Evaporated milk, when partially diluted, often gives good results.

Giving the orphan lamb supplemental vitamin A in either the oral or injectable form may also help get him off to a faster start. A single dose of no less than 25,000 international units (I.U.) of vitamin A per lamb should be adequate. If the lamb received plenty of colostrum then the vitamin A supplement might not be necessary.

Feed orphan lambs 1 to 2 ounces of milk every two or three hours from early morning until late evening for the first few days. Gradually increase the volume of milk per feeding and the length of time between feedings. After about two weeks feed only 3 or 4 times daily.

A regular medicine bottle with a standard-size nipple works well for feeding the lamb during the first few days. As the lamb grows older a pop bottle with a standard-size nipple will be satisfactory. If quite a few pet lambs are to be fed, then a multiple lamb feeder, either commercial or home-made, would be better.

Provide the lambs with a creep ration when they are 7 to 10 days of age. The sooner the lambs begin to eat supplemental feed the faster they will grow. Soybean meal has been found to be an excellent feed for very young lambs.

Individual Performance Differences

The period of greatest performance difference between single lambs and lambs of multiple birth is within the first 30 days, when the lambs are relying primarily on the ewe for their source of food. As lambs begin to eat supplemental feed the differences in gain decrease, and somewhere between 60 and 90 days of age twins usually catch up with singles in rate of gain. The data in Table 3 help point out this tendency. Wether lambs usually gain at about the same rate as ewe lambs from birth to 90 days of age, but ram lambs normally gain from 3.5 to 7 pounds more during the same period.

“In-and-Out” System of Lamb Management

If lambs are not sold before going to pasture, the “in-and-out” system of lamb management may be practical. There are several alternative procedures in this system:

1. Keep ewes and lambs together in drylot at night, but place them on separate pastures during the day.
2. Keep ewes and lambs together in drylot during the day, but place them on separate pastures at night.
3. Keep ewes and lambs together in drylot at night, place ewes on pasture during the day, and keep lambs in the barn on creep feeders.
4. Keep ewes and lambs together in drylot during the day, place ewes on pasture at night, and keep lambs in the barn on creep feeders.

The “in-and-out” system tends to cut down internal parasite problems and improves lamb performance during the pasture season.

Weaning

The proper age to wean lambs depends primarily on the system of management followed. These factors influence the age at which lambs are weaned: when the lambs are born (early or late); percentage of multiple births; creep feeding; availability of grain or pasture; parasite problems; type of sheep raised; and market prices and price outlook.

Most lambs in the midwestern states are weaned between two and five months of age. Late lambs that reach market weight on pasture are usually weaned at an older age than early lambs that are creep-fed. In recent years there has been more interest in earlier weaning. One reason is that milk production usually reaches a peak three or four weeks after lambing and decreases thereafter. Three or four months after lambing most ewes will be producing very little milk and it would be more economical to wean the lambs and turn the ewes out to pasture or at least decrease their daily ration. Many flock owners now wean at 90 days.
of age or less with good results, and some research done on weaning at 30 to 60 days of age has had good results. Wean spring lambs that are on hand July 1. Weaning will enable lambs to reach market earlier and avoid late summer hazards of hot weather, poor pastures, and parasite buildups. Worm, drench, and shear the lambs and vaccinate them for overeating disease. Shorn lambs will be more comfortable, will gain faster, and will grade higher when sold. When weaned lambs are fed on good parasite-free legume or legume-grass pasture, the grain ration may consist of only corn or a mixture of corn and other grains. If you feed lambs in drylot, the ration should contain at least 13 percent crude protein. Feed a good-quality legume or mixed hay free choice, in addition to the grain ration unless a complete ground and mixed ration or pelleted ration is used.

**MANAGEMENT ON PASTURE**

Your sheep will get the most out of pastures if you do as follows:

1. Wait until pastures are ready before turning in the flock. Most forage should be 4 to 6 inches high before being grazed. Sorghum-sudangrass hybrids should be approximately 18 inches high before being grazed.

2. Use a moderate stocking rate to prevent close grazing. Stocking rates will vary with pasture forage used, season, and fertility level. If pastures become short because of drought or overstocking, wean the lambs. The illustration on the facing page shows pasture grazing periods and the normal stocking rates for Illinois pastures.

3. If possible, rotate pastures at two- to three-week intervals. Clip pastures at the end of each grazing period to encourage new growth, retain legumes in the pasture mixture, and control weeds. Grazing with cattle will increase pasture yields.

4. Provide clean water and shade.

**FEEDING THE STUD RAM**

Even though there has been very little research work dealing with nutrition of the stud ram, some general recommendations can be made. The stud ram, like the brood ewe, requires adequate nutrition in order to perform efficiently. Poor nutrition can result in lowered fertility or even infertility, as well as loss of vigor and strength. For best results the ram should be in moderate condition at breeding time.
In the summer and just before the breeding season the ram can receive all of its nutrient requirements from pasture. If the ram begins to lose weight during the breeding season or if he is thin before the breeding season, he should receive from 1 to 1 1/2 pounds per day of a concentrate mixture similar to that recommended for ewes. If a ram lamb is being used he should be fed more than this.

The above illustration indicates pasture grazing periods and carrying capacities (ewes per acre) for Illinois. Actual carrying capacities will vary with rainfall, temperature, fertility, season, and stand.
During the winter months feed the ram so that he gains some weight but does not become excessively fat. One pound of a concentrate mixture and 3½ to 4 pounds of legume or mixed hay should be enough for a 180-pound ram. Feed a 240- to 250-pound ram the same level of concentrate and 4½ to 5 pounds of hay per day. When silage is fed, substitute 2 to 3 pounds of silage for each pound of hay replaced.

**PARASITE CONTROL**

Failure to effectively control internal and external parasites can result in greatly decreased performances of ewes and lambs. Severe cases of parasitism often cause death. Good parasite control is one of the management practices that pays big dividends.

**Internal Parasites**

The most common internal parasite is the stomach worm. Tape-worms and lung worms are also found in many Illinois flocks. Therefore, parasite control programs are directed primarily toward the control of these three. Other internal parasites, such as smaller round worms, nodular worms, whip worms, and liver flukes, are occasionally reported. If you suspect your sheep have these internal parasites, your veterinarian can identify them and suggest proper treatment.

For the most effective control of internal parasites, drench the brood flock and replacement stock at least three or four times a year: once
before turning sheep out to pasture in the spring; once or twice during the summer and early fall; and again when the sheep are brought into the barn for the winter. Lambs that are born early and are marketed without going to pasture will usually not need drenching. Those that are to go on pasture should be drenched regularly the same as the brood flock.

Don’t use the same drench throughout the year, but alternate at least two different ones. If you use only one product the parasites that are not eliminated may become at least partly immune to it. Four common drenching materials are phenothiazine, phenothiazine-arsenate of lead, combination drench (copper sulfate-nicotine sulfate), and thiabendazole.

Allow sheep free access to a phenothiazine-trace-mineralized salt mixture during the pasture season. Providing rotation pasture or rotating sheep on permanent pasture is also an effective means of reducing internal parasite problems.

**External Parasites**

External parasites can be controlled best by following a yearly dipping program. Use a toxaphene solution or other dipping preparations recommended for livestock use and recognized by the USDA and the Illinois Department of Agriculture. Ticks, lice, and mites can be very detrimental to the performance of sheep of all ages, and especially detrimental to the quality and value of the wool produced.

Ticks are probably the most common external sheep parasites. They are brown, have six legs, are about 3/16 to 1/4 inch long, and can be easily seen when the fleece is parted. By sucking blood from the skin of sheep, ticks cause irritation, restlessness, rubbing, and loss of wool.

There are two kinds of sheep lice, the biting louse and the sucking louse. The more common is the red-headed biting louse. It is very small — seldom more than 1/25 of an inch long — and looks much like a timothy seed. You can see lice either in the wool or on the skin. The damages to sheep are mainly an irritation of the skin which causes sheep to rub off their wool and an unthrifty condition caused by restlessness.

Four species of mites affect sheep: the psoroptic or scab mite, the chorioptic or foot scab mite, the sarcoptic or head scab mite, and the psorergates mite, which lives between the layers of skin. The psoroptic, commonly called sheep scab mite, causes the greatest damage to flocks. It is one of the most destructive external parasites and also one of the most difficult to control. This parasite is only 1/50 of an inch long and burrows into the skin. The sheep rubs itself and pulls at the wool to relieve the irritation and itching. Hard scabs form in the affected areas and the sheep loses condition rapidly. Since sheep scab is such a highly infectious disease, treatment must be prompt and effective. Federal and
state programs are under way to eliminate scabies from the United States.

Dipping should be done on a bright, sunny day if possible, but do not wait for the ideal day if scab has been diagnosed. Few farms have permanent dipping vats, but portable dipping vats are available throughout much of the state. If neither type is available, the sheep may be sprayed. Spraying calls for more material and is usually not so effective as dipping. Dusting is a difficult and dirty job and less effective than either dipping or spraying. The operator should wear a respirator for protection when he is dusting.

FOOT HEALTH

It is very important to keep the feet of all sheep well trimmed. Foot problems prevent sheep from performing at the highest level. These problems are much easier to prevent than to cure.

Suggestions for Foot Care

1. Trim the feet of all sheep twice a year. Use a sharp knife, pruning shears, or foot-rot shears.
2. Sell for slaughter all sheep that do not respond to treatment.

The picture on the left shows a sheep with one hoof that needs trimming and one that is properly trimmed. A commonly used foot trimmer is also shown. Note in the picture on the right how much better the sheep can stand on the hoof that has been properly trimmed.
3. Isolate all new sheep until their feet have been carefully inspected and trimmed.

4. Do not allow sheep to travel through deep mud or manure.

5. Catch lame sheep and examine their feet as soon as you notice the lameness.

6. To minimize pasture contamination, isolate all sheep that have any type of foot infection.

Foot problems may be caused by foot rot, foot abscess, and foot scald; lack of timely and proper foot care; poor foot development caused by tissue abnormalities, nutrition, and genetics; injury from cinders, gravel, and plant stubbles; and lip and foot diseases, such as contagious ecthyma.

Foot Rot

Foot rot affects sheep of all ages and lameness is usually the first symptom noticed. Animals that are not treated seldom recover readily and they remain carriers. The disease can spread rapidly through the flock, and one or more feet may become infected. The outer horny portion of the hoof frequently separates from the sole. The separation usually progresses from the heel to the toe. There is not a large amount of pus, but gray necrotic material separates the horny portion from the underlying flesh of the hoof. Foot rot is characterized by a strong odor of the affected tissue.

Foot Abscess

Foot abscess differs greatly from foot rot. The abscess frequently affects a single foot at a time and may even be limited to half of the foot. Generally there is no odor, or if there is odor, it is hard to define. In the early stages pressure on the claw causes pain. Later a boil-like abscess appears, with swelling, inflammation, and proud flesh which bleeds freely. Yellowish-green pus erupts at the coronet or higher up. Like a boil, it discharges gray or yellow necrotic material. The abscess usually heals with time and is not considered highly infectious or contagious. The germ is passed in the dung of the sheep.

Foot Scald

Foot scald is a mild irritation of the area between the sheep’s toes. It occurs during wet weather and causes lameness. Foot scald can be con-

\[\text{Material taken from "Sheep Raising in Ohio" by Grimshaw, Bell, and Judy, 1963.}\]
trolled by clipping areas of the pastures where the sheep lie to reduce the incubation effect of the wet, warm pasture.

**Footbath Solutions**

If a footbath is needed, use a solution of 20 to 25 percent copper sulfate, 5 to 10 percent formalin, or 10 percent quaternary ammonia. Let sheep stand in a footbath for at least 3 to 4 minutes, and treat every second day for eight days. Follow a sound yearly foot-health program to minimize foot troubles.

**LAMB MARKETING**

Lamb prices usually reach a high in June and decline to a December low. In many years a 90- to 95-pound choice lamb marketed in June has grossed as much as a 115-pound lamb sold in November and December.

Heavy-muscled, fast-gaining lambs like the one pictured at the right bring top prices on today's markets. Such lambs produce trim, muscular carcasses like the one shown below. Some of the best lambs have loin eyes larger than 3 square inches (see enlargement below).
Lambs carried through late summer also gain weight more slowly, have gains that are more expensive, have more parasites, grade lower, and have more death losses.

Top out lambs as they reach 90 to 100 pounds and grade choice or prime. At times they can be carried to 110 pounds without being penalized for heavy weights. However, later in the season they should weigh 90 to 100 pounds and grade at least choice to bring top prices.

Suckling lambs will shrink a great deal en route to market. To reduce shrink, you should sort, transport, and weigh them in as short a time as possible. Try to sort spring lambs for shipment the day they are to be sold.

Most Illinois lambs are sold through terminal markets, local pools, and auctions. However, some large commercial flocks move lambs on a direct basis by selling either to a packer representative or an order buyer. Your choice of a market will depend on current prices, markets in your area, numbers of lambs you have to sell, and available transportation.

Easter lambs are milk-fat lambs weighing 40 to 45 pounds. They are sold to meet the demand during the Easter season. Although the price per pound for Easter lambs may seem high, the most important consideration in selling to this specialty market is the number of dollars you will receive per head. Lambs that are ready for the Easter market in late March or April will probably weigh 90 to 100 pounds in June, the normal peak in spring lamb prices, so you must figure carefully to see what will be the most profitable way to market such lambs.

**WOOL PRODUCTION AND MARKETING**

**Value of Wool**

Harvest the wool crop carefully, for it is a valuable product. Wool is one of the highest priced products sold from the farm, and in many cases it is one of the most poorly managed. It accounts for 15 to 30 percent of the gross returns from sheep.

Fleece weights of brood ewes and rams are important. For example, take two extremes, one ewe shearing 7 pounds and another shearing 14 pounds. With wool, including incentive payment, at 65 cents a pound and lamb at 24 cents a pound, the light-shearing ewe would have to raise 19 pounds more lamb than the heavy-shearing ewe in order to produce the same gross income. It may be well worth your time to pay more attention to the fleece weights of your breeding stock.

**Care and Marketing of Fleeces**

When you shear sheep and handle fleeces, there are certain important procedures to follow:
1. Shear only when the wool is dry.
2. Shear on a clean, dry surface.
3. Avoid second cuts; remove the fleece in one piece.
4. Remove all tags, dung locks, and stained wool from the fleece, and bag them separately.
5. Roll fleece with the flesh side out and tie securely, but not too tightly, into a neat package.
6. Use paper twine for tying fleeces.
7. Store the tied fleeces in a wool bag in a clean, dry area that is protected from dust, dirt, and rodents.

Fleeces that are full of hay, straw, manure, mud, or other foreign matter are greatly reduced in value. If you live in an area that holds a wool pool, it may be to your advantage to market through the pool. At least check present wool prices before you sell to local buyers so you will have an idea what your wool is worth.

Following the proper method makes shearing much easier for the shearer and the sheep. This picture was taken at one of the four sheep shearing schools that are conducted in Illinois each spring.
Wool Grades

Since January 1, 1966, new U. S. standards for grades of wool have been in effect. The new standards designate 16 numerical grades, four more than existed previously, and were designed to give the wool industry a more precise and objective means of evaluating wool grades. The grades still retain their traditional numbers, which originally reflected spinning count. Spinning count is based on the number of hanks of yarn (each hank is 560 yards in length) that can be spun from one pound of wool top.

The new standards specify average fiber diameter limits for each grade in terms of microns (1/25,400 of an inch). Each grade also contains limits on the variation in diameter allowed among the individual fibers in the lot. If the variability of the individual fibers is greater than the limits specified in the standards, the wool will be graded the next lower grade.

The new standards provide for the grading of wool by both visual appraisal and actual measurement of fiber diameter.

Before January 1, 1966, the American or blood system and the numerical system were both commonly used; however, producers generally refer to the blood system when discussing wool grades. In this system wool is placed into one of seven major grades based on diameter of fiber. A comparison of the official U. S. grades and the blood system follows.

Here a properly tied fleece is being inspected for staple length and grade. Note the wool bag in the background where the fleece will be stored until sold. Note also that the shearing floor has been kept clean.

Marketing Wool

Selling your wool for the best possible price is important. A higher price per pound not only means a larger check when sold, but a larger wool incentive payment. Most Illinois wool clips are marketed through area wool pools, consigned to wool marketing cooperatives in neighboring states, or sold to wool buyers or their representatives.

When wool is delivered to area wool pools, each fleece is graded according to fineness, length, color, and cleanliness. Each producer’s clip is weighed by grade and stored with other fleeces of the same grade. At the end of the pool, the wool is sold by grade on a sealed bid basis. Each consignor is paid for his consignment on the basis of grade and sales price.

Wool cooperatives from several neighboring states are accepting wool on a consignment basis through Illinois points. When wool is delivered to one of these points, it is weighed and a cash advance or partial payment is made. The wool is shipped to the cooperative’s warehouse, where it is fleece-graded. Each grade is weighed and stored or shipped with other wool of the same grade. The consignor receives final settlement on the basis of grade and price received for that grade, minus the amount of the cash advance.

Wool sold to local dealers is usually sold on a cash basis. Many shearsers also buy wool on this basis. These outlets may or may not pay a price differential for various grades.
