

AN IMPLICIT BIAS TO GENERALIZE TO CATEGORIES:
EVIDENCE FROM MEMORY ERRORS

Abstract

We propose that humans have an implicit bias to generalize information about the members of a category to the category itself, when appropriate. This proposal complements recent arguments that category- or kind-based reasoning is particularly low-effort and may thus be privileged in human cognition (e.g., Hampton, 2012; Leslie & Gelman, 2012). To test our proposal, we asked participants to remember two types of novel facts: kind-wide (generic) facts (e.g., facts about *zorbs*) and universally quantified facts (e.g., facts about *all stups*). Half of the facts concerned properties that are typically generalizable to an animal kind (e.g., eating fruits and vegetables), and half concerned properties that are typically more idiosyncratic (e.g., getting mud in their hair). We predicted that, due to the hypothesized bias, participants would *spontaneously generalize* the quantified facts about generalizable properties to the corresponding kinds, and would do so more frequently than for the facts about idiosyncratic properties. In turn, these implicit generalizations would lead to a higher rate of quantified-to-generic memory conversions for the generalizable properties. The results of Experiments 1 and 2 were consistent with this prediction. Moreover, the same generalizable versus idiosyncratic difference occurred under cognitive load (Experiment 1), suggesting that the hypothesized bias requires few cognitive resources, and when controlling for potential differences across these two types of properties in the similarity/confusability of quantified and generic statements (Experiment 2). Experiment 3 ruled out the possibility that these results were an artifact of the memory clues provided to participants. These studies provide evidence for our proposal of an implicit bias to draw generalizations about kinds.

Acknowledgements

The completion of this project is due, in large part, to many others. First, I would like to thank my advisor, Andrei Cimpian, for the many hours that he dedicated to not only this project, but also to fostering my research and writing skills generally. I am also very grateful for my collaborators on this project, Sarah-Jane Leslie and Susan Gelman, for their support and continued feedback. I would like to thank Renee Baillargeon for her thorough review and helpful comments on this thesis. Many others have supported me throughout the work hours spent towards this project, a few of whom are Liam Baird, Lin Bian, Larisa Hussak, Michelle Miernicki, and Christina Tworek. I am extremely thankful for my family's continued support and encouragement. And, I am appreciative of all of the lab members in the U of I Cognitive Development Lab. Finally, I am grateful for the financial support provided by NSERC.

Chapter 1: Introduction

Humans conceive of the world as being populated not just by unique individuals (e.g., the tall leafy thing in the front yard) but also by kinds of things (e.g., trees). What's more, we routinely acquire and store knowledge at the level of these abstract kinds, and we use this knowledge with amazing flexibility to communicate with one another, explain the world around us, and predict future outcomes (e.g., Gelman, 2003; Markman, 1989; Murphy, 2004; Smith & Medin, 1981). These achievements are all the more remarkable considering that we do not in fact have perceptual access to kinds per se—only to particular samples. To some researchers, the accumulated evidence in the psychology of concepts has suggested that, beyond being merely capable of reasoning about kinds, human cognition may actually be structured so as to privilege the processing of information at this general level (e.g., Gelman, 2010; Hampton, 2012; Hollander, Gelman, & Star, 2002; Leslie, 2008, 2012).

According to these arguments, reasoning about kinds requires few cognitive resources compared to reasoning about sets of comparable scope. Consider some of the developmental evidence on this point. Children's ability to evaluate claims about entire kinds (e.g., "Do *girls* have curly hair?") is adult-like starting at around the age of 3, whereas their ability to evaluate claims about similarly broad quantified sets (e.g., "Do *all girls* have curly hair?") has a much more protracted developmental course (Hollander et al., 2002; Mannheim, Gelman, Escalante, Huayhua, & Puma, 2011; Tardif, Gelman, Fu, & Zhu, 2012). This developmental pattern—which has been found in children learning languages from three different language families (English, Mandarin, and Quechua)—is particularly striking when taking into account the fact that, from the perspective of formal semantics, statements about kinds are more complex than quantified statements. To illustrate the formal complexity of statements about kinds (or generic

statements), consider that one can truthfully say that *mosquitoes carry malaria* but not that *books are paperbacks*, even though the majority of books are paperbacks, and only a tiny percentage of mosquitoes carry malaria (e.g., Prasada, Khemlani, Leslie, & Glucksberg, 2013). Because of puzzling examples such as these, a formal account of the truth conditions of generic statements has eluded semanticists for over 40 years (e.g., Carlson & Pelletier, 1995; Lawler, 1973; but see Leslie, 2008). In contrast, specifying the truth conditions for quantified statements is often formally simple (e.g., the truth of a universally quantified statement is determined by a clear rule: the statement is true only if every single category member has the described property). Thus, the cognitive ease with which children understand generics (which are formally complex), coupled with the cognitive difficulties children encounter with quantified claims (which are formally simple), is suggestive of a bias in the architecture of our cognitive systems—a bias that enables reasoning about kinds to be so effortless that even young children can perform such formally complex reasoning competently.

These ease-of-processing claims (i.e., that reasoning about kinds requires few cognitive resources) are not restricted to children. For instance, when adults have to evaluate or remember quantified facts, they often respond as if these facts were about kinds (Leslie & Gelman, 2012; Leslie, Khemlani, & Glucksberg, 2011; Meyer, Gelman, & Stilwell, 2011). To illustrate, Leslie and Gelman (2012) asked children and adults to remember both generic facts (e.g., “Bees have five eyes”) and quantified facts (e.g., “All bees have five eyes”) for a later memory test. At both ages, participants were more likely to mistakenly recall quantified statements as being instead generics, rather than recalling generics as quantified statements. This result, which was bolstered by follow-up studies ruling out alternative explanations, seems consistent with the ease-of-processing argument above: If quantified information is more cognitively challenging to process

and store than the corresponding generic information, then participants may inadvertently default to the latter and thus recall quantified information as generic.

Evidence for the ease-of-processing account is also provided by Hampton's (2012) argument concerning the relative difficulty of *extensional* and *intensional* reasoning (see also Jönsson & Hampton, 2006; Tversky & Kahneman, 1983). According to Hampton, extensional reasoning (that is, reasoning in terms of frequencies and sets) is more cognitively demanding than intensional reasoning (that is, reasoning in terms of kinds and their generic properties). As a result, when people are asked to reason extensionally (e.g., to judge the truth value of a universally quantified statement), they often fail to do so and instead inadvertently fall back on an intensional, kind-based mode of reasoning, leading to characteristic errors of judgment (e.g., mistakenly judging the truth value of a universally quantified statement as if it were generic; see also Leslie, Khemlani, & Glucksberg, 2011).

In the present paper, we identify a new, and powerful, bias that encourages the formation of kind representations. Specifically, we propose that human cognition may be biased to spontaneously generalize information about particular samples to the entire relevant kinds whenever such generalizations are warranted. Similar to the ease-of-processing bias described above, this *generalization bias* gives rise to many kind representations that we would not have formed otherwise. However, the process by which it does so is quite different: The kind representations created through the hypothesized generalization bias are not the byproducts of an inability to process quantified information—they are not the side effects of our cognitive limitations. Rather, they are the outcome of inferences (inductive generalizations, to be more precise) that our cognitive systems perform when encountering quantified information about sets of objects in the world. We should also clarify that these generalizations are not performed

because of a conscious, explicit intention to do so; the hypothesized generalization bias is *implicit*. Just as people make spontaneous inferences about, say, an individual's traits and goals without really intending to do so (e.g., Gilbert & Malone, 1995; Uleman, Saribay, & Gonzalez, 2008), our account proposes that people spontaneously, and implicitly, generalize quantified evidence about particular samples (e.g., these trees have leaves) to the level of entire categories (e.g., trees have leaves).

Our proposal of a generalization bias is consistent with the research suggesting that people are quite willing to draw kind-wide conclusions from relatively sparse evidence. For example, adults often judge that a property that is present in a minority of the members of a kind (e.g., 30% of morseths have silver fur) is likely to be true of the kind as a whole (e.g., morseths, as a kind, have silver fur; Cimpian, Brandone, & Gelman, 2010). Similarly, the developmental literature on inductive inferences has suggested that even very young children generalize information from one member of a kind to another arbitrary member—and thus, arguably, to the entire kind (e.g., Keates & Graham, 2008; Gelman & Markman, 1986, 1987; Graham, Kilbreath, & Welder, 2004; Sutherland & Friedman, 2012, in press; see also Cimpian & Park, in press; Csibra & Gergely, 2009).

These findings, however, do not provide evidence for a bias to draw spontaneous kind generalizations. These previous results suggest that people will often draw conclusions about kinds *when they are provided with explicit opportunities to do so*. For instance, Cimpian and colleagues' (2010) data show that people generalize certain quantified facts to the level of kinds when they are asked whether these generalizations are warranted. It is unclear, however, if people would have drawn the generic conclusions they did without the experimenter's prompt. To make strong claims about an implicit bias to generalize to categories, we would need

evidence that this hypothesized bias provides an impetus to generalize in the absence of external incentives—or, perhaps, even in the presence of *disincentives*.

In the studies reported here, we tested whether people *spontaneously* generalize quantified evidence to the level of a kind in the context of a task that *discourages* such generalizations (because they lead to incorrect answers). The task, modeled after Leslie and Gelman (2012), is ostensibly about people’s memory for generic and quantified facts about novel animals. In reality, however, our reason for adopting it was that it can reveal whether people use the evidence provided by the quantified facts (e.g., *all zorbs* eat fruits and vegetables) to draw spontaneous generalizations about the relevant kinds (e.g., *zorbs* eat fruits and vegetables). If participants did so, their gist memory for the quantified facts would arguably be influenced by these generalizations; as a result, they may misremember some of the facts that were originally quantified as being generic on a memory test. Such generalization-induced memory errors, if they occurred, would be both spontaneous (rather than externally prompted) and counter to the incentive structure of the task (where accurate memory was the only criterion for success). Thus, from the novel perspective outlined here, the evidence from this task could speak to the presence of an implicit bias to generalize to categories.

The use of this memory paradigm, however, gives rise to an obvious problem: The prediction of our generalization bias is at this point indistinguishable from that of the ease-of-processing bias—both predict frequent conversions from quantified to generic form, albeit for different reasons: In contrast to our account, the ease-of-processing account suggests that these conversions are not a result of spontaneous generalizations but rather of the resource-intensive nature of processing quantified information, which should lead participants to inadvertently fall back on the easier-to-process kind representations. To circumvent this ambiguity, we

manipulated the content of the facts participants were asked to remember. That is, half of the facts described properties that are typically *generalizable* to an entire animal kind (e.g., diet, habitat), whereas the other half described properties that are typically *idiosyncratic* to a particular individual (e.g., temporary states, accidents). Given the extensive evidence that kind generalizations are sensitive to the content of the property being generalized (e.g., Cimpian et al., 2010; Cimpian & Markman, 2008; Gelman, 1988; Gelman & Markman, 1986; Shipley, 1993), the hypothesized generalization bias should be correspondingly sensitive to the content of the facts. That is, people should be more likely to spontaneously make kind generalizations when the quantified evidence concerns properties that would *plausibly* apply to an entire animal kind than when the quantified evidence concerns properties that are typically not kind-relevant. As a result, people should be significantly more likely to misremember quantified facts as generic when the facts are about generalizable properties than when they are about idiosyncratic properties.

Importantly, this prediction is distinct from the prediction of the ease-of-processing claim, which provides no reason to expect an asymmetry in memory errors for generic and quantified facts based on the content of the properties they describe. The ease-of-processing account would instead predict that a quantified fact, regardless of what type of property it is about, is still quantified and thus would be more cognitively taxing to remember, causing people to fall back on an easier-to-process kind representation.

Given that the generalization bias is hypothesized to be implicit, we might further hypothesize that it requires minimal cognitive resources for its operation, working quietly “behind the scenes” to enrich our conceptual knowledge. We explored this issue empirically by placing half of the participants under a cognitive load while they were encoding the quantified and generic statements. If the bias to generalize to kinds operates without requiring much

cognitive effort, then the participants who are under cognitive load should also misremember the quantified facts as generic more often when these facts are about generalizable (vs. idiosyncratic) properties.

To summarize, we proposed that people have an implicit bias to generalize information about particular samples to the level of entire categories. If such a bias were in place, then it is likely that one symptom of it would be a tendency to make spontaneous kind generalizations more often in contexts where the evidence at hand licensed such generalizations. In the current memory paradigm, these spontaneous generalizations should lead people to recall quantified facts as generic more often when these facts are about generalizable properties than when they are about idiosyncratic properties. By manipulating whether participants had to perform a concurrent task while encoding the generic and quantified facts, we were also able to test whether this bias requires only minimal cognitive resources to operate. Experiments 1 and 2 provide consistent evidence for these predictions. In addition, Experiments 2 and 3 address two alternative explanations for the findings.

Chapter 2: Experiment 1

2.1 Method

Participants. The participants were 187 undergraduate students from a large public university in the Midwestern US. All were native English speakers. The reward for participation was course credit or \$5. Participants were randomly assigned to either a No Load ($n = 93$) or a Cognitive Load ($n = 94$) condition.

Items. We used 16 facts about novel animals (see Table 1), each of which could be presented either as universally quantified (e.g., “All zorbs eat fruits and vegetables”) or as generic (e.g., “Zorbs eat fruits and vegetables”). However, the same fact was never presented in both forms to the same participant. In addition, half of the facts described generalizable properties (e.g., eating fruits and vegetables), and half described idiosyncratic properties (e.g., getting mud in their hair). The generalizable and idiosyncratic properties were matched in length (both $M_s = 4.75$ words). Moreover, in a separate norming study, we asked participants ($N = 43$) to judge how many members of a kind were likely to possess these properties (e.g., “If you had to guess, what percentage of stups get mud in their hair?”) given that at least one member of the kind had the property. The results confirmed that all of the generalizable properties were indeed judged to be more generalizable (range = 75.1% to 85.7% of category members have the property) than all of the idiosyncratic properties (range = 14.0% to 55.4%); this difference was significant, $M_{generalizable} = 80.9\%$ versus $M_{idiosyncratic} = 42.2\%$, $t(42) = 9.56$, $p < .001$.

The 16 facts were presented in one of three random orders, each of which had two versions. The three random orders were generated with the constraint that no more than three facts of the same form (i.e., “all” or generic) or containing the same type of property (i.e., generalizable or idiosyncratic) should occur in a row. The two versions of each order were

identical except with respect to the generic/universal form of each fact: If a fact was generic in one version, it was universally quantified in the other version, and vice versa.

Procedure and Design. Testing occurred in small groups of up to six participants. To avoid overwhelming participants' memory capacity, the 16 facts were split into two blocks of eight, each of which contained four facts in generic form and four in "all" form, as well as four generalizable and four idiosyncratic properties. The same three-phase procedure, described next, was followed for both blocks.

1) Learning phase. In the No Load condition, the experimenter asked participants to pay close attention for a later recall test. Then, she read aloud the eight facts from the first block. As the participants listened to the facts, they followed along in a booklet. Each page in this booklet contained a line drawing of the novel animal that was referenced in the corresponding fact. The procedure for the Cognitive Load condition was identical, except that participants were also asked to rehearse a string of six digits while listening to the facts and following along in their booklets. Immediately after listening to the facts, participants were asked to recall the digits in the order in which they were presented (for similar methods of inducing cognitive demands, see Baddeley & Hitch, 1974; Gilbert & Hixon, 1991).

2) Distractor phase. All participants were then asked to complete a four-minute distractor task in which they completed a series of multi-digit multiplication problems.

3) Recall phase. Next, participants received a second booklet with the same drawings as the booklet from the learning phase. Participants were asked to go through the booklet and write what they remembered of the sentences that the experimenter had read for each page. Because our main interest was in participants' memory for the scope of the facts (generic vs. "all") rather than in their memory for the content of these facts, we provided two strong clues to the content

of each sentence: the bare singular form of the relevant novel noun (e.g., zorb) and an additional noun from the fact (e.g., vegetable; see Table 1 for full list of clues).

Once participants finished writing down their recall responses for the first block, the three phases (learning, distractor, and recall) were repeated for the second block of eight sentences.¹

The design of our study can be summarized as follows: 2 (fact form: generic vs. “all”; within subject) × 2 (property type: generalizable vs. idiosyncratic; within subject) × 2 (cognitive load: load vs. no load; between subjects).

Coding. One researcher coded participants’ recalled sentences into one of three mutually exclusive categories depending on their scope: generic, “all,” and “other” (which also included failures to recall anything). If a sentence was about a kind as a whole (e.g., “Zorbs like to eat vegetables”), it was coded as generic.² If a sentence was about all members of a kind (e.g., “All zorbs eat fruits and vegetables”), it was coded as “all.” If a sentence was about a single instance of a kind³ or had indeterminate scope (e.g., “Eat fruits and vegetables”), it was coded as “other.” These three categories accounted for 49.7%, 31.0%, and 19.4% of participants’ responses, respectively. A second researcher, blind to the load condition and the original form of the fact,

¹ Approximately half of the participants received a slight variant of this procedure, in which (1) the booklets used during the learning phase listed the same two clues as those in the recall phase (rather than no clues), and (2) the Cognitive Load condition involved rehearsing a string of eight digits (rather than six). Because this procedural variant did not interact significantly with either of the variables of interest (property type and cognitive load), we report the data collapsed across it.

² The vast majority of sentences coded as generic had either bare plural noun phrases (e.g., “Reesles like to swim in the ocean”) or indefinite singular noun phrases (e.g., “A dax stores its food in its cheeks”) in the subject position. However, we also coded as generic a number of sentences with (what appeared to be) bare singular noun phrases in the subject position (e.g., “Glippet keep their nests on mountain peaks”). This coding decision was based on the assumption that some participants may have been unsure of how to pluralize the novel nouns provided (e.g., some may have thought that the plural of *glippet* may be *glippet*, on analogy with *sheep* or *deer*). This latter type of generic accounted for only 5.3% of responses coded as generic. Moreover, when the data were analyzed without these generics, the results replicated those reported in the main text. Also note that we did not code definite singular noun phrases as generic. Even though such noun phrases can in principle refer to a kind, their generic use is rare (e.g., Gelman, Coley, Rosengren, Hartman, & Pappas, 1998). Moreover, since one of the clues provided to participants was a picture of a *single* exemplar from the relevant category, the task context made it very likely that subjects’ definite singular nouns (e.g., “the oller”) were referring to the exemplars on the page in front of them.

³ Statements about single instances accounted for 11.8% of responses ($M_{generalizable} = 10.6\%$; $M_{idiosyncratic} = 13.0\%$).

coded the responses of 167 of the 187 subjects (20 subjects were used for training). Cohen's kappas for the generic, "all," and "other" coding categories were .97, 1.0, and .95, respectively, and disagreements were resolved through discussion.

We also coded Cognitive Load participants' memory for the digits they were asked to rehearse while they were listening to the facts. Two researchers independently rated each participant's recalled digit strings on a scale from 1 [completely wrong or missing] to 5 [completely correct].⁴ Inter-rater agreement was high, $r = .93$. Each subject's final rating was the average of the two researchers' ratings, except in cases where their scores differed by more than one point. In such cases, the researchers discussed the disagreement and reached a mutually agreeable rating.

Dependent Measure. In light of the prior evidence for the efficiency of kind-based computations (e.g., Hollander et al., 2002; Leslie & Gelman, 2012), it is likely that participants will, on the whole, be more likely to mistakenly recall "all" statements as generic rather than the reverse. Our proposal of a bias to generalize to categories makes two additional predictions: (1) the magnitude of the asymmetry in memory errors across fact form (i.e., more "all"-to-generic than generic-to-"all" conversion errors) should be greater when the facts concern generalizable properties than when they concern idiosyncratic properties, and (2) this property effect should be observed even when participants have few cognitive resources available.

To test these predictions, we calculated the difference score between "all"-to-generic and generic-to-"all" memory conversions, separately for the generalizable and the idiosyncratic properties. This calculation proceeded in two steps. First, we calculated the percentage of statements that were originally presented in "all" form (eight per participant) that were instead

⁴ The intermediary scale points were labeled as follows: 2 [very few correct numbers in the correct order], 3 [some of the correct numbers in the correct order], and 4 [minor errors (e.g., one number missing or out of order)].

recalled in generic form, and the percentage of statements originally presented in generic form (eight per participant) that were instead recalled in “all” form. These conversion scores were calculated for each individual participant, separately for the generalizable and idiosyncratic properties. Second, we took each participant’s percentages of “all”-to-generic conversions and subtracted from them the participant’s percentages of generic-to-“all” conversions, again separately for the generalizable and idiosyncratic properties. Thus, each participant received two final difference scores (one for each property type), which we will refer to as *generalization-bias scores* from here on.

Our predictions can be assessed by testing, first, whether participants’ generalization-bias scores are higher for facts that describe generalizable properties than for facts that describe idiosyncratic properties, and second, whether this difference is present both when cognitive resources are intact and when they are taxed.

2.2 Results

Data Analysis Strategy. Participants’ generalization-bias scores clustered in the upper half of the range and were thus non-normally distributed (Shapiro-Wilk test, $p < .001$). Because of this violation of parametric assumptions, we analyzed the data using ordinal logistic regressions (OLRs) computed using the Generalized Estimating Equations command in SPSS. Cognitive load was a between-subjects factor in this analysis, and property type was a within-subject factor.⁵

Cognitive Load Manipulation Checks. If participants in the Cognitive Load condition complied with our instructions to rehearse the string of digits provided by the experimenter, then they should have reasonably accurate memory for these digits. Very poor digit recall is most

⁵ Despite the assumption violations, the results of the OLRs were replicated with analyses of variance (ANOVAs).

likely a sign that the subjects did not rehearse the digits and were not actually under a cognitive load (see Gilbert & Hixon, 1991, for a similar argument). Thus, we excluded from the analyses any subjects whose average digit memory scores were below 2 on the 1–5 scale described in the Method ($n = 13$; $M_{digit\ memory} = 1.37$). This left 81 subjects in the Cognitive Load condition. (Note that all of the significant results reported below remain significant even if these subjects are not excluded.)

As an additional check that the 81 remaining Cognitive Load participants were indeed under a load, we tested their accuracy on the primary task (fact recall) relative to the participants in the No Load condition. If the cognitive load imposed a burden on working memory resources, Cognitive Load participants should have less accurate memory compared to participants in the No Load condition. Consistent with this prediction, Cognitive Load participants were significantly less likely than No Load participants to recall the facts in the correct form ($M_s = 38.0\%$ and 52.2% of responses were recalled in the correct form, respectively), Wald $\chi^2(1) = 28.98$, $p < .001$, $d = 0.75$ (see also Table 2 and the Appendix). Thus, it seems reasonable to assume that our cognitive load manipulation was successful in inducing different cognitive demands on the two groups of participants.

First Prediction: A Main Effect of Property Type. To reiterate, we proposed that people have an implicit bias to make kind generalizations. In the context of our task, this bias might prompt spontaneous generalizations to the kind level especially when the evidence warrants such generalizations. Thus, when a novel property is generalizable—the sort of property that is typically true of kinds—participants may be particularly likely to make implicit inferences using the quantified evidence at hand (e.g., “All zorbs eat fruits and vegetables”) to generalize to the kind itself (e.g., zorbs, as a kind, have this sort of diet). These generalizations, should they

occur, would lead to higher generalization-bias scores for generalizable properties than for idiosyncratic properties. In line with this prediction, the OLR revealed a significant main effect of property type, such that participants had higher generalization-bias scores for facts about generalizable properties ($M = 24.1\%$ more “all”-to-generic than generic-to-“all” conversions) than for facts about idiosyncratic properties ($M = 16.0\%$), Wald $\chi^2(1) = 12.11$, $p = .001$, $d = .13$.⁶

We also explored whether the effect of property type held up at the level of individual participants. Specifically, we compared the number of participants who had higher generalization-bias scores for the generalizable than for the idiosyncratic properties with the number of participants who had the opposite pattern (higher generalization-bias scores for idiosyncratic properties). Consistent with our prediction, there were significantly more participants with higher generalization-bias scores for the generalizable properties (37.9% of participants) than participants with higher generalization-bias scores for the idiosyncratic properties (17.8% of participants), $p < .001$ by a sign test.

Second Prediction: An Effect of Property Type in Both the Cognitive Load and the No Load Conditions. We also hypothesized that the bias to generalize to kinds operates without much cognitive effort. Thus, our second prediction was that this bias should influence participants’ memory regardless of whether or not they are asked to perform another task while listening to the experimenter’s facts. In other words, we predicted that there would be a statistically significant effect of property type in both the No Load and the Cognitive Load conditions. We did not, however, make a priori predictions about whether we would obtain a significant Property Type \times Cognitive Load interaction. On the one hand, it is possible that the

⁶ These generalization-bias scores were significantly greater than zero both for the generalizable properties (one-sample Wilcoxon test, $Z = 4.92$, $p < .001$) and for the idiosyncratic properties (one-sample Wilcoxon test, $Z = 3.13$, $p = .002$), indicating that there were significantly more “all”-to-generic than generic-to-“all” conversions for both of these types of facts. These differences are consistent with prior evidence (e.g., Leslie & Gelman, 2012) that suggests a *general* tendency to misremember quantified information instead as generic.

hypothesized bias to make kind inferences would require so few resources that it would be wholly insensitive to different levels of cognitive demands (Logan, 1979); in this case, no significant interaction should be found. We were open, however, to the possibility that subjects under a cognitive load might be prevented from drawing as many kind inferences as they would otherwise, which could lead to a smaller (but, we predict, still significant) difference between the generalization-bias scores for generalizable and idiosyncratic properties. In sum, we did not make strong predictions about whether there would be a significant Property Type \times Cognitive Load interaction—only that the effect of property type would be significant in both conditions.

Consistent with our prediction, participants' generalization-bias scores were higher for statements that described generalizable properties than statements that described idiosyncratic properties, both for those who were not under load, Wald $\chi^2(1) = 6.63, p = .010, d = 0.15$, and for those under a cognitive load, Wald $\chi^2(1) = 5.41, p = .020, d = 0.12$. Additionally, there was no significant difference between the magnitude of the property type effect in each load condition, as the OLR revealed no trace of an interaction between property type and cognitive load, Wald $\chi^2(1) = 0.08, p = .782$ (see Table 2 and the Appendix for means).⁷

Individual participants' response patterns pointed to the same conclusion: There were significantly more participants who had higher generalization-bias scores for the generalizable (vs. the idiosyncratic) properties than participants who had higher scores for the idiosyncratic (vs. the generalizable) properties in both the No Load and the Cognitive Load conditions, $ps = .005$ and $.053$, respectively, by sign tests.

2.3 Discussion

To summarize, we found that participants were more likely to misremember quantified

⁷ The main effect of cognitive load was not significant either, $M_{No\ Load} = 18.3\%$ vs. $M_{Cognitive\ Load} = 22.1\%$ more “all”-to-generic than generic-to-“all” conversions, Wald $\chi^2(1) = 0.15, p = .696, d = 0.06$.

facts as generic (rather than vice-versa) when these facts were about properties that are typically generalizable to a kind (e.g., “All zorbs eat fruits and vegetables”) than when they were about properties that are typically more idiosyncratic (e.g., “All stups get mud in their hair”). This finding is in line with our main proposal that people have an implicit bias to make spontaneous kind generalizations and are therefore likely to generalize quantified evidence to kinds whenever such generalizations are warranted.

There is, however, an alternative explanation for these findings. Perhaps people don’t generalize the quantified evidence about generalizable properties to the relevant kinds, as we hypothesized. Rather, universally quantified and generic statements may simply be *closer in their meaning*—and thus *more confusable*—when they describe generalizable properties than when they describe idiosyncratic properties. For instance, hearing that “zorbs eat fruits and vegetables” might lead people to expect that the vast majority of zorbs do so (Cimpian et al., 2010), which would then make this statement similar in meaning with a statement such as “All zorbs eat fruits and vegetables.” If generic and “all” statements are seen as meaning roughly the same thing in this particular case, then people might just produce the shorter of the two statements at recall, leading to an increased rate of “all”-to-generic conversions compared to generic-to-“all” conversions. (Again, no kind generalizations of the sort we hypothesize are invoked by this alternative account.) In contrast, generic statements about idiosyncratic properties (e.g., “Stups get mud in their hair”) may *not* be seen as being similar/confusable in meaning with the corresponding universally quantified statements (e.g., “All stups get mud in their hair”), in part because generics about such properties suggest relatively low prevalence levels (Cimpian et al., 2010, Experiment 3). For idiosyncratic properties, then, people may be *less* inclined to use the shorter generic statements as stand-ins for universally quantified

statements (because their meanings are not seen as interchangeable), leading to lower, and more symmetrical, numbers of “all”-to-generic and generic-to-“all” errors.

Although intuitively plausible, this alternative cannot explain other aspects of the results obtained in Experiment 1. For example, if generic and “all” statements are more confusable for generalizable properties, then it is hard to explain why the percentage of correct responses for these properties ($M = 46.5\%$) was nearly identical to the percentage of correct responses for the supposedly less-confusable generic and “all” statements about idiosyncratic properties ($M = 44.8\%$; Wilcoxon $Z = 1.23$, $p = .222$). The confusability alternative straightforwardly predicts that people should be correct *less often* for the generalizable properties. This result, however, is suggestive but not conclusive, so we conducted Experiment 2 in order to provide a more definitive test of this alternative explanation. Specifically, we measured and statistically adjusted for the perceived similarity/confusability of “all” and generic statements about generalizable and idiosyncratic properties. If the confusability alternative were correct, then taking participants’ judgments of meaning similarity into account when testing for an effect of property type should eliminate the difference in generalization-bias scores observed in Experiment 1. In contrast, we predicted that the effect of property type on generalization-bias scores would replicate even when controlling for this measure of similarity/confusability.

Chapter 3: Experiment 2

3.1 Method

Participants. Eighty-six participants were recruited using Amazon’s Mechanical Turk platform and completed the study online. All were native English speakers residing in the US. The reward for participation was \$0.75.

Items. We used the same items as in Experiment 1.

Procedure. The procedure was similar to the No Load condition of Experiment 1, with a few methodological changes necessitated by (1) the switch from in-lab to online testing, and (2) the addition of the key control variable of this experiment (namely, similarity/confusability).

The changes were as follows. First, instead of listening to the sentences while looking at a booklet, participants read the sentences on their computer screens, each on a separate page. Each page was programmed to automatically advance after 15 seconds in order to equate encoding time across sentences. To ensure that the participants attended to the stimulus sentences, we also required them to type out these sentences in a text box on the page on which they were displayed. Second, the distractor phase was shortened to two minutes rather than four. A two-minute delay is more in line with the brevity of typical studies on Mechanical Turk, and yet it is still long enough to ensure that participants had to rely on long-term memory at recall (e.g., Peterson & Peterson, 1959). Third, the distractor task consisted of arithmetic problems that could be solved without needing a pen and paper, unlike the multi-digit multiplication problems used in Experiment 1. Fourth, to assess the similarity/confusability of “all” and generic statements describing generalizable and idiosyncratic properties, we presented participants with all 16 pairs of generic and “all” statements (e.g., “Stups get mud in their hair” and “All stups get mud in their hair”; see Table 1) and asked them to rate how similar in meaning these pairs were

(“How similar are the meanings of these two sentences?”). Participants marked their answers on a 10-point scale (from 1 = “very dissimilar” to 10 = “very similar”). Each pair was presented on a different screen. The order of the 16 pairs was randomized for each subject. Also, the order in which the generic and “all” sentences were displayed within the pairs was randomized across participants. These rating questions were always presented after the recall phase so as to not interfere with the memory task.

Because online testing makes cheating on the memory task a possibility, at the very end of the session we asked participants to report whether they had written down, copied, or used any other external sources to help them remember the sentences. To encourage truthful responses, we made it very clear to participants that they would receive payment regardless of how they answered this question. Two participants reported cheating and were excluded, leaving 84 participants in our sample.

Coding. The coding scheme was the same as in Experiment 1. Inter-coder agreement was calculated over all 84 transcripts and was again excellent: Cohen’s kappas for the generic, “all,” and “other” coding categories were .97, .99, and .94, respectively. Disagreements were resolved through discussion.

Dependent Measures. Generalization-bias scores were calculated just as in Experiment 1, by taking the difference between “all”-to-generic and generic-to-“all” memory conversions separately for the generalizable and the idiosyncratic properties. Participants’ similarity scores were also calculated separately for the two property types by averaging the similarity ratings for the eight generalizable items and the eight idiosyncratic items.

3.2 Results and Discussion

Our claim is that people make more asymmetric memory errors (more “all”-to-generic

than generic-to-“all” conversions) for generalizable than for idiosyncratic properties because of an implicit bias to generalize to kinds, and not because of low-level factors having to do with the confusability of generic and universally quantified statements describing these types of properties. Thus, we predicted that generalization-bias scores would be significantly higher for the generalizable than for the idiosyncratic properties *even when adjusting for any differences between the similarity/confusability of “all” and generic statements about the two property types*.

To begin, we examined whether such similarity/confusability differences exist in the first place. Participants did in fact rate universally quantified and generic statements as being more similar when they described generalizable properties ($M = 8.34$ on a 1–10 scale, $SD = 1.37$) than when they described idiosyncratic properties ($M = 8.05$, $SD = 1.56$), Wilcoxon $Z = 3.63$, $p < .001$. Importantly, however, this difference did not account for the difference found between generalization-bias scores for generalizable and idiosyncratic facts. We submitted participants’ generalization-bias scores to an OLR with property type (generalizable vs. idiosyncratic) as a predictor and similarity/confusability scores as a covariate. As predicted, the main effect of property type was replicated even when controlling for the similarity variable: Participants had significantly higher generalization-bias scores for the generalizable properties ($M = 34.5\%$ more “all”-to-generic than generic-to-“all” conversions) than for the idiosyncratic properties ($M = 25.3\%$), Wald $\chi^2(1) = 7.37$, $p = .007$, $d = .15$. (We report unadjusted means here and in Table 2 and the Appendix.) Moreover, the similarity/confusability covariate was not a significant predictor of generalization-bias scores, Wald $\chi^2(1) = 1.11$, $p = .292$.^{8,9}

⁸ The same results were found with a repeated-measures ANOVA with similarity/confusability as a covariate.

⁹ As an additional means of investigating whether the difference in similarity/confusability was related to the difference in generalization-bias scores between generalizable and idiosyncratic properties, we calculated the correlation between (1) a generalization-bias difference score (generalization-bias score for generalizable properties

As in Experiment 1, the main effect of property type was replicated at the level of individual participants. There were significantly more participants with generalization-bias scores in the predicted direction (generalizable > idiosyncratic; 33.3%) than participants with generalization-bias scores in the unpredicted direction (idiosyncratic > generalizable; 14.3%), $p = .017$ by a sign test.

These findings speak against the possibility that participants' responses in our task are due to a similarity/confusability confound. Instead, it seems more likely that participants are spontaneously generalizing the provided quantified information to the relevant kinds whenever appropriate, revealing an implicit bias to generalize to kinds.

minus generalization-bias score for idiosyncratic properties) and (2) a similarity/confusability difference score (similarity score for generalizable properties minus similarity score for idiosyncratic properties). This correlation was non-significant, $r(82) = -.08$, $p = .448$, which speaks against the alternative hypothesis tested here and is consistent with the non-significant covariate effect reported in the main text.

Chapter 4: Experiment 3

In this experiment, we addressed an additional alternative explanation for our findings. According to this alternative, participants' responses in Experiments 1 and 2 could have been driven entirely by the clues given during the recall phase. To elaborate, the clue words provided for the generalizable properties in those experiments were slightly different in content from the clue words provided for the idiosyncratic properties (see Table 1): More of the clues for generalizable properties referred to typical animal habitats (e.g., ocean, mountain) and diets (e.g., vegetables). Given that elements such as habitats and diets often figure in kind-wide properties, participants who saw these clues during the recall phase may have been artificially induced to generate statements about kinds *even if they hadn't drawn any kind inferences from the original statements* (or, for that matter, even if they didn't remember anything about the original statements). It is possible, then, that this asymmetry in the content of the memory clues used in the first two studies might explain the greater number of "all"-to-generic (vs. generic-to-"all") errors for generalizable properties than for idiosyncratic properties. Experiment 3 was conducted to investigate this alternative explanation. Specifically, we presented a new group of participants with the clues (both pictures and words) given during the recall phase of Experiments 1 and 2 and asked them to generate either generic or universally quantified statements using these clues. If the clues alone were driving our effect, we should find more generic responses for the clues provided for generalizable properties in the first two studies compared to clues provided for the idiosyncratic properties. In contrast, we predict that there will be no difference in the number of generic responses between the two sets of clues.

4.1 Method

Participants. Eighty-seven participants were recruited using Amazon's Mechanical Turk

platform and completed the study online. All were native English speakers residing in the US. The reward for participation was \$0.75.

Procedure. We asked participants to *create* sentences using exactly the same clues that were shown in the recall phase of Experiments 1 and 2. We also provided a few rules to guide participants' sentence creation; these rules were meant to ensure that their expectations about the types of sentences they were supposed to generate were similar to those of participants who had previously gone through a learning phase (Experiments 1 and 2). Specifically, we asked participants to (1) generate full sentences, to (2) begin their sentences with either bare plural nouns (e.g., "zorbs") or universally quantified nouns (e.g., "all zorbs"), and to (3) avoid using the same type of beginning across all 16 sentences they would be asked to create. Participants were also told that the second clue could be used in another form than it was given ("For example, if you are given the word 'eye,' you can use the word 'eyes' in your sentence instead"). These rules were reiterated on each trial, so that participants didn't have to remember them. Across participants, we randomized the order in which the two types of noun phrases (bare plural and universally quantified) were mentioned in the rules, so as to avoid biasing participants toward using one or the other.

Coding. The same coding criteria were used as in Experiments 1 and 2. However, because the instructions provided in this study explicitly limited participants' responses to sentences beginning with bare plural nouns or universally quantified nouns, there were almost no responses that were ambiguous in scope.¹⁰ As a result, we did not ask a second researcher to code participants' responses in this study.

¹⁰ Although instructing participants to begin their sentence with a bare plural does not guarantee that they will produce a generic statement, in fact in this study they almost always did.

4.2 Results and Discussion

There was no difference in the number of generic sentences participants generated for clues previously provided for facts describing generalizable properties ($M = 60.1\%$ of all responses) and for clues previously provided for facts describing idiosyncratic properties ($M = 61.4\%$), Wilcoxon $Z = 0.72$, $p = .470$.¹¹ This result suggests that our findings in Experiments 1 and 2—namely, the higher generalization-bias scores for generalizable properties than for idiosyncratic properties—were not an artifact of the clues provided during the recall phase. Instead, it is more likely that participants were actually *misremembering* the quantified generalizable facts as being about the relevant categories, arguably because of the hypothesized bias to make kind generalizations.

¹¹ Participants produced more generic responses than would be expected by chance (50%) for both sets of clues, one-sample Wilcoxon $Zs = 4.27$ and 4.79 , $ps < .001$, for the generalizable and the idiosyncratic property clues, respectively.

Chapter 5: General Discussion

Our findings across three studies provide evidence for an implicit, but powerful, bias to generalize to kinds. In Experiments 1 and 2, participants were more likely to misremember quantified statements as generic (rather than the reverse) when those statements described generalizable properties as opposed to when they described idiosyncratic properties. This difference was also found when participants were under additional cognitive demands (Experiment 1), suggesting that the hypothesized bias can operate “under the radar,” without taking up much cognitive capacity. Our findings also ruled out two alternative explanations. In Experiment 2, we found that the predicted difference in generalization-bias scores between facts that describe generalizable and idiosyncratic properties persisted when controlling for the perceived similarity/confusability of the “all” and generic forms of these facts. In Experiment 3, we demonstrated that the clues provided in the recall phase of Experiments 1 and 2 could not have been responsible for the differences observed in generalization-bias scores. Together, these studies are consistent with our proposal that people have an implicit bias to make kind generalizations—to spontaneously generalize novel information to kinds when such generalizations are justifiable.

To highlight the striking nature of these results, we should point out that there are valid considerations that could have prompted participants to convert universal statements about *idiosyncratic* properties to generic form, which would have led to a pattern opposite of what we actually observed. Typically, idiosyncratic properties of the sort used in our study apply to fewer category members than generalizable properties do (e.g., the norming study in the Method of Experiment 1; Cimpian et al., 2010). As a result, universally quantified statements about idiosyncratic properties (e.g., “*All* stups get mud in their hair”) are less plausible than analogous

statements about generalizable properties (e.g., “All zorbs eat fruits and vegetables”). In principle, then, participants could have preferred to convert universal statements about idiosyncratic properties to generic form because generic statements can plausibly be true even if there is little statistical evidence to support them (e.g., Cimpian et al., 2010; Leslie, 2008). The fact that participants converted instead more of the universal statements about *generalizable* properties to generic form, despite the fact that they were plausible as is, strengthens our claim that participants’ behavior in our task was driven by a bias to generalize to kinds.¹²

It is also important to note that the present results cannot be explained by, and thus go beyond, an ease-of-processing bias of the sort previously proposed in the literature (e.g., Hampton, 2012; Leslie & Gelman, 2012). If the only factor driving participants’ responses in our task had been a relative difference in the difficulty of processing quantified and generic statements (with quantified statements being more effort-intensive to understand, evaluate, store, etc., than generic statements), then participants should have converted an equal number of quantified statements to generic form across the two property types. The ease-of-processing account alone does not predict that quantified statements vary in their computational complexity depending on whether they refer to, say, eating fruits and vegetables or getting mud in one’s hair. Thus, the greater asymmetry between the number of “all”-to-generic and generic-to-“all” memory conversions we observed for generalizable relative to idiosyncratic properties is most compatible with, and was predicted a priori by, our argument that human cognition is biased to generalize evidence about quantified samples to the entire relevant kinds whenever such generalizations are warranted. From a broader perspective, the presence of such a bias is likely to

¹² Although the analyses reported in the main text focused on the generalization-bias scores, not “all”-to-generic conversions per se, there were in fact significantly more “all”-to-generic conversions for the generalizable properties than for the idiosyncratic properties (Experiment 1: Wald $\chi^2(1) = 13.69$, $p < .001$; Experiment 2: Wald $\chi^2(1) = 11.70$, $p = .001$).

have a powerful impact on the development of our conceptual knowledge, facilitating the acquisition of a tremendous amount of category knowledge from experience with particular samples.

Returning to the present study, our results also suggest that the bias to draw kind inferences might operate without making many demands on cognitive resources. We base this conclusion on the fact that the effect of property type (i.e., higher generalization-bias scores for generalizable than for idiosyncratic properties) was equally strong for participants who were under a cognitive load as for those who were not. Thus, the implicit bias to generalize to kinds may function not just when people have the luxury of explicitly focusing on learning about categories. Rather, this fundamental bias probably operates under most everyday circumstances, even when we are engaged in other activities and not deliberately trying to acquire generic knowledge.

Our proposal of a bias to generalize to kinds is compatible in spirit with previous hypotheses and evidence from the developmental literature that highlight the privileged status of kind representations in human cognition. Consider, for example, the recent claims of an early—perhaps even innate—sensitivity to social cues that signal the transmission of generic knowledge (Csibra & Gergely, 2006, 2009). To illustrate, communicative cues such as eye contact and pointing to an object lead 9-month-olds to encode and remember kind-relevant properties of that object (e.g., shape, color) rather than kind-irrelevant ones (e.g., location; Yoon, Johnson, & Csibra, 2008; see also Futó, Téglás, Csibra, & Gergely, 2010; Butler & Markman, 2012). Such ostensive/pedagogical contexts have also been shown to elicit higher rates of generic language (Gelman, Ware, Manczak, & Graham, 2013), which provides a very effective means of conveying generic knowledge and is understood by children as young as 2 and 3 (e.g., Cimpian

& Markman, 2008; Cimpian, Meltzer, & Markman, 2011; Gelman & Raman, 2003; Graham, Nayer, & Gelman, 2011). Also related to our present argument, Cimpian and Erickson (2012) demonstrated that preschool-age children are better able to recall information that pertains to a kind compared to identical information about an individual. Children's ability to retain kind knowledge faithfully in long-term memory dovetails nicely with the proposed implicit bias to generalize to kinds and thereby acquire such kind knowledge.

In conclusion, the current findings suggest that the human mind may be biased to make spontaneous kind generalizations whenever the evidence at hand allows such generalizations. This bias is likely to exert a powerful—yet often unnoticed—influence on our learning, guiding us towards knowledge at the level of abstract kinds.

Tables

Table 1

The 16 items, in generic and universally quantified format

Property Type	Fact Format	
	Generic	Universally Quantified
Generalizable^a	Cheebas sleep through the winter	All cheebas sleep through the winter
	Daxes keep food in their cheeks	All daxes keep food in their cheeks
	Reesles like to swim in the ocean	All reesles like to swim in the ocean
	Blins sweat through their paws	All blins sweat through their paws
	Mooks shed their skin every year	All mooks shed their skin every year
	Zorbs eat fruits and vegetables	All zorbs eat fruits and vegetables
	Lorches taste with their feet	All lorches taste with their feet
	Glippets build their nests on mountain peaks	All glippets build their nests on mountain peaks
Idiosyncratic^b	Stups get mud in their hair	All stups get mud in their hair
	Ollers have broken legs	All ollers have broken legs
	Ackles get fungus infections in their ears	All ackles get fungus infections in their ears
	Kweps chip their teeth on nuts	All kweps chip their teeth on nuts
	Zoovs fall out of trees while sleeping	All zoovs fall out of trees while sleeping
	Kazzes trip over logs and rocks	All kazzes trip over logs and rocks
	Sapers twist their ankles	All sapers twist their ankles
	Flooms get dust on their faces	All flooms get dust on their faces

^aThe memory clues for the *generalizable* properties were as follows: “cheeba” and “winter,” “dax” and “cheek,” “reesle” and “ocean,” “blin” and “paw,” “mook” and “skin,” “zorb” and “vegetable,” “lorch” and “foot,” “glippet” and “mountain.”

^bThe memory clues for the *idiosyncratic* properties were as follows: “stup” and “hair,” “oller” and “leg,” “ackle” and “ear,” “kwep” and “tooth,” “zoov” and “tree,” “kazz” and “rock,” “saper” and “ankle,” “floom” and “face.”

Table 2

Average percentages for various measures in Experiments 1 and 2, by property type and cognitive load (standard deviations in parentheses below)

Measure	Generalizable Properties			Idiosyncratic Properties		
	Expt. 1		Expt. 2	Expt. 1		Expt. 2
	Cog. Load (N = 81)	No Load (N = 93)	No Load (N = 84)	Cog. Load (N = 81)	No Load (N = 93)	No Load (N = 84)
Generalization-bias score (“all”-to-generic minus generic-to-“all” conversions)	25.6 (62.6)	22.8 (61.6)	34.5 (60.1)	18.5 (60.7)	13.7 (63.6)	25.3 (59.0)
“All”-to-generic conversions (originally presented “all” statements recalled as generic)	47.8 (40.9)	48.1 (37.1)	56.8 (37.3)	39.8 (37.9)	43.3 (34.2)	47.6 (36.9)
“All” – correct (originally presented “all” statements recalled as “all”)	27.8 (33.8)	41.4 (37.1)	29.8 (34.8)	28.4 (33.7)	44.6 (37.0)	37.8 (35.5)
“All” – other (originally presented “all” statements recalled as neither “all” nor generic, or not recalled)	24.4 (31.6)	10.5 (24.3)	13.4 (28.9)	31.8 (35.1)	12.1 (23.2)	14.6 (26.9)
Generic-to-“all” conversions (originally presented generic statements recalled as “all”)	22.2 (29.6)	25.3 (32.0)	22.3 (31.3)	21.3 (30.9)	29.6 (35.9)	22.3 (30.3)
Generic – correct (originally presented generic statements recalled as generic)	50.3 (38.8)	64.5 (35.4)	64.6 (35.8)	45.7 (39.7)	58.3 (36.9)	61.9 (34.4)
Generic – other (originally presented generic statements recalled as neither generic nor “all,” or not recalled)	27.5 (33.7)	10.2 (23.1)	13.1 (27.0)	33.0 (34.4)	12.1 (25.7)	15.8 (29.8)

Note. The three “all” rows add up to 100% (within each column), as do the three generic rows.

Appendix

Table 3

Raw averages for various measures in Experiments 1 and 2, by property type and cognitive load (standard deviations in parentheses below)

Measure	Generalizable Properties			Idiosyncratic Properties		
	Expt. 1		Expt. 2	Expt. 1		Expt. 2
	Cog. Load (<i>N</i> = 81)	No Load (<i>N</i> = 93)	No Load (<i>N</i> = 84)	Cog. Load (<i>N</i> = 81)	No Load (<i>N</i> = 93)	No Load (<i>N</i> = 84)
Generalization-bias score (“all”-to-generic minus generic-to-“all” conversions)	1.02 (2.50)	0.91 (2.47)	1.38 (2.40)	0.74 (2.43)	0.55 (2.54)	1.01 (2.36)
“All”-to-generic conversions (originally presented “all” statements recalled as generic)	1.91 (1.64)	1.92 (1.48)	2.27 (1.49)	1.59 (1.51)	1.73 (1.37)	1.90 (1.48)
“All” – correct (originally presented “all” statements recalled as “all”)	1.11 (1.35)	1.66 (1.49)	1.19 (1.39)	1.14 (1.35)	1.78 (1.48)	1.51 (1.42)
“All” – other (originally presented “all” statements recalled as neither “all” nor generic, or not recalled)	0.98 (1.26)	0.42 (0.97)	0.54 (1.16)	1.27 (1.41)	0.48 (0.93)	0.58 (1.08)
Generic-to-“all” conversions (originally presented generic statements recalled as “all”)	0.89 (1.18)	1.01 (1.28)	0.89 (1.25)	0.85 (1.24)	1.18 (1.44)	0.89 (1.21)
Generic – correct (originally presented generic statements recalled as generic)	2.01 (1.55)	2.58 (1.42)	2.58 (1.43)	1.83 (1.59)	2.33 (1.48)	2.48 (1.38)
Generic – other (originally presented generic statements recalled as neither generic nor “all,” or not recalled)	1.10 (1.35)	0.41 (0.92)	0.52 (1.08)	1.32 (1.38)	0.48 (1.03)	0.63 (1.19)

Note. The three “all” rows add up to 4 (within each column), as do the three generic rows.
